arXiv:submit/8260035 [cs.LG] 20 Oct 2026

Abstract

The prevailing scaling paradigm of Large Language Models (LLMs) rests on a substrate of "Fuzzy" floating-point arithmetic. To mitigate the inherent instability of this approximate foundation, modern architectures have erected a complex scaffolding of structural and numerical heuristics—Complex Residuals, Pre-RMSNorm, Attention Scaling, and Gradient Clipping—consuming significant compute solely to prevent numerical collapse.

We propose a paradigm shift to the "Exact". We introduce the **Halo Architecture**, grounded in the Rational Field ($\mathbb{Q}$) and powered by a custom Exact Inference Unit (EIU). To resolve the exponential bit-width growth of rational arithmetic, Halo employs a **Dual-Ring Topology** that unifies two complementary control mechanisms: (1) The **Micro-Ring** (Continuum Maintenance), which strictly bounds memory complexity via Diophantine Approximation; and (2) The **Macro-Ring** (Symbolic Alignment), which enforces logical consistency via periodic state collapse.

This stable dual-ring substrate allows for the **"Great Dismantling"** of numerical scaffolding, reducing the Transformer block to its **"Clean"** algebraic form (Tabula Rasa). Furthermore, we verify the **"Efficiency Paradox"**: the elimination of gradient noise ($\sigma \to 0$) allows for Macro-Learning Rates, potentially reducing the Total Time-to-Convergence by orders of magnitude. Halo demonstrates that General Intelligence requires the hybridization of continuous fields and discrete chains under a rigorous mathematical framework.

1 INTRODUCTION

The "Scaling Laws" of Large Language Models (LLMs) have driven the industry towards lower-precision formats (FP16, BF16, and recently FP8) to maximize matrix multiplication throughput Kaplan et al. [2020]. While effective for intuitive pattern matching, this strategy shows diminishing returns for tasks involving multi-step reasoning, symbolic manipulation, and long-horizon planning.

We argue that this is due to a fundamental mismatch between the physical substrate (approximate floating-point hardware) and the mathematical requirements of rigorous logic. Logic is discrete and precise; floating-point arithmetic is continuous and approximate. We observe that in deep recursive inference, numerical noise ϵ accumulates exponentially ($\mathcal{O}(e^L)$), eventually drowning out the causal signal. We term this phenomenon **Semantic Drift**. This aligns with recent findings by Thinking Machines Lab [2025], who pinpointed floating-point non-associativity as the culprit for inference instability.

To survive this instability, modern architectures have erected a complex scaffolding of structural and numerical heuristics—**Complex Residuals, LayerNorm, Attention Scaling, and Gradient Clipping**—consuming significant compute solely to prevent numerical collapse. We term this **"Numerical Debt."**

In this work, we propose the **Halo Architecture**, which transitions the computational foundation from the approximate field of real numbers ($\mathbb{R}$) to the exact field of rational numbers ($\mathbb{Q}$). We ensure that operations such as $1/3+1/3+1/3$ yield exactly 1, rather than 0.9999999.

However, Halo goes beyond mere exactness. To resolve the tractability of rational arithmetic, we introduce a **Dual-Ring Topology**. This unifies two complementary control mechanisms: the **Micro-Ring** (Continuum Maintenance), which utilizes **Diophantine Approximation** to bound numerical variance with quadratic error decay ($\mathcal{O}(D^{-2})$); and the **Macro-Ring** (Symbolic Alignment), which periodically

collapses the state to enforce logical consistency. This stable substrate allows us to perform the **"Great Dismantling"**—abolishing all numerical scaffolding to restore the Transformer to its **Clean** algebraic form.

Contributions.

1. **The Exactness Hypothesis:** We formally link "Semantic Drift" in deep reasoning to the numerical instability of floating-point arithmetic, and argue that, under the bounded per-layer operator growth assumed in Assumption 1, $\mathbb{Q}$ provides a sufficient substrate for infinite-depth logic.
2. **The Dual-Ring Topology:** We introduce a hierarchical control architecture. The **Micro-Ring** handles continuous numerical tractability (The Wave), while the **Macro-Ring** enforces discrete logical consistency (The Particle).
3. **The Clean Transformer:** Leveraging the stability of the Dual-Ring, we demonstrate the abolition of "Numerical Band-aids" (LayerNorm, Scaling, Clipping), restoring the Transformer to its pristine algebraic form.
4. **The Exact Inference Unit (EIU):** We propose a hardware specification featuring CRT-based RNS acceleration and Dual-Modular Redundancy, resolving the efficiency and reliability bottlenecks of exact computation.

Silicon Feasibility: Dispelling the "Exactness is Slow and Expensive" Myth. A prevalent preconception in the AI hardware community is that abandoning floating-point shortcuts for exact rational arithmetic necessitates astronomical silicon area and crippling inference latency. We challenge this dogma by demonstrating that the Exact Inference Unit (EIU) is not merely physically realizable, but fundamentally competitive with—and in key aspects superior to—modern commercial GPU Tensor Cores:

- **Area and Density Feasibility (Eliminating FPU Bloat):** Modern GPU Tensor Cores dedicate substantial silicon real estate and wire routing to IEEE 754 control complexity: dynamic exponent alignment shifters, leading-zero anticipation (LZA), denormal flush circuits, and multi-mode rounding controllers. The EIU datapath completely purges floating-point logic, consisting *strictly of uniform integer multiply-accumulate (MAC) arrays and barrel shifters*—the most area-efficient and routing-friendly primitives in deep-submicron CMOS (e.g., 3nm/5nm). Synthesized on equivalent silicon budgets, the EIU achieves comparable or superior standard-cell transistor density.
- **Speed and Throughput Parity via Decoupled Asynchrony:** The EIU decouples execution from simplification. By employing wide 4096-bit registers as temporal accumulation buffers (*Lazy Reduction*), tens of consecutive matrix products proceed without triggering algebraic reduction. Furthermore, through an asynchronous "Fire-and-Forget" pipeline, irreducible canonicalization ($\gcd(n, d) = 1$) is offloaded to background shift-subtract binary Stein cores running concurrently. Because matrix contraction intensity scales as $\mathcal{O}(N^3)$ while GCD overhead scales at $\mathcal{O}(N)$, the arithmetic cost of exactness is asymptotically hidden behind systolic tensor execution, matching the clock-rate throughput of dense FP16/BF16 GEMM engines.
- **Deterministic Energy Efficiency:** By replacing iterative floating-point division and transcendental microcode with exact rational Taylor/Padé expansions and deterministic integer logic, the EIU eliminates speculative execution bubbles and normalization pipeline stalls, significantly enhancing performance-per-watt efficiency in long-context inference.

2 RELATED WORK

Numerical Stability in Deep Learning. The fragility of floating-point arithmetic in recursive systems is well-documented in dynamical systems theory [Lozej and Robnik, 2021]. Recent work by Thinking Machines Lab [2025] highlighted non-associativity as a source of inference non-determinism. While techniques like *Quantization Aware Training (QAT)* [Jacob et al., 2018] attempt to make models robust to low precision, they treat noise as a constraint to be managed. Halo departs from this by treating noise as an error to be eliminated, shifting the paradigm from "Robust Approximation" to "Exact Computation."

Information Bottleneck & Discrete Representation. The "Ring" mechanism draws theoretical grounding from the Information Bottleneck (IB) principle [Tishby et al., 2000]. By periodically collapsing the continuous rational stream into a low-complexity codebook, we explicitly filter out "nuisance variables" (high-frequency numerical noise) while preserving "relevant variables" (logical structure). This aligns with Vector Quantized VAEs (VQ-VAE) [Van Den Oord et al., 2017], but whereas VQ-VAE learns a codebook for compression, Halo uses the axiomatic field $\mathbb{Q}$ as a "Universal Codebook" for logical grounding.

Recurrent Depth Architectures Recent explorations into scaling "test-time compute," such as the Huginn-0125 prototype[Geiping et al., 2025], have proposed decoupling parameter count from reasoning depth via latent loops. However, these attempts revealed a critical barrier: models relying on standard BF16 arithmetic suffer from "state collapse" (divergence) after approximately 50 recurrent steps. We view these findings not as architectural failures, but as empirical evidence of the "Precision Wall." Halo provides the necessary numerical substrate (Exact Rational Arithmetic) to

stabilize these infinite-depth architectures, enabling them to fulfill their theoretical promise.

Hallucination as a Numerical Artifact The prevailing view attributes LLM hallucinations to data contamination or probabilistic decoding errors [Ji et al., 2023]. We propose an alternative, complementary hypothesis: that a significant subset of "logical hallucinations" (e.g., arithmetic errors, causal inconsistencies) are artifacts of *Numerical Uncertainty*. In chaotic systems, microscopic floating-point errors (ϵ) amplify exponentially over time [Lozej and Robnik, 2021], causing the model's internal state to drift off the logical manifold. Halo eliminates this source of error, suggesting that exactness is a prerequisite for faithfulness.

Floating-Point Instability The peril of floating-point arithmetic is well-documented in scientific computing [Goldberg, 1991, Higham, 2002], yet largely ignored in modern LLM training. While low-precision formats (FP8, BF16) suffice for statistical pattern matching [Micikevicius et al., 2018], dynamical systems theory suggests that deep recurrent architectures operate near the "edge of chaos". Halo solves this by shifting the arithmetic substrate from $\mathbb{R}$ to $\mathbb{Q}$.

Neuro-Symbolic AI & Neural Arithmetic Halo shares the goal of Neuro-Symbolic AI [Mao et al., 2019] but rejects the separation of "Neural" and "Symbolic" modules. Instead, we internalize exactness into the weights themselves. Similarly, unlike NALU [Trask et al., 2018] which attempted arithmetic via gating in float space, Halo achieves true arithmetic capability by adopting a rational number system.

Historical Foundations of Exact Computation The pursuit of exactness in computer arithmetic has a rich lineage. In the 1980s, Matula and Kornerup [1985] pioneered the "Slash Number System," exploring hardware-level finite precision rational arithmetic via continued fractions. The Halo Micro-Ring's Diophantine Approximation conceptually inherits this lineage, extending optimal rational convergence to the extreme bit-widths ($B_{max} = 4096$) required by modern deep reasoning. Similarly, our critique of catastrophic cancellation in floating-point dot products builds upon the foundational work of Kulisch [2013], who advocated for the Exact Dot Product via massively wide accumulators. This concept was later popularized as the "Quire" in Posit arithmetic [Gustafson and Yonemoto, 2017]. We explicitly treat the Quire as a relevant baseline; however, whereas a monolithic Quire suffers from carry-chain latency, the Halo Exact Inference Unit (EIU) resolves this by deploying parallel Residue Number System (RNS) channels based on the Chinese Remainder Theorem, functioning as a distributed, highly concurrent Quire. Finally, while our conceptual framing of Rational Interval Enclosures draws from Shewchuk's principles of robust geometric predicates [Shewchuk, 1997], we diverge architecturally: rather than deploying adaptive dynamic precision which incurs severe control-flow overhead, Halo resolves decision boundaries statically by over-provisioning the datapath precision to theoretical extremes, rendering boundary collisions probabilistically negligible.

3 THE EXACTNESS HYPOTHESIS

Just as the *Scaling Hypothesis* [Kaplan et al., 2020] posits that performance scales with compute, our **Exactness Hypothesis** posits that reasoning depth scales with numerical precision.

3.1 THE BUTTERFLY EFFECT IN HIGH-DIMENSIONAL SPACE

Deep neural networks are highly non-linear dynamic systems. Let $f(x)$ be a transformer block. A deep network is the composition $F(x) = f_L(\dots f_1(x))$. In current hardware, each layer computation introduces a truncation error ϵ_i.

$$\hat{y} = f_L(f_{L-1}(\dots(x + \epsilon_0)\dots) + \epsilon_{L-1}) + \epsilon_L \quad (1)$$

For statistical tasks (e.g., image classification), this noise is negligible. However, for AGI-level tasks involving N-step logical deduction, the error growth is exponential, akin to the butterfly effect in chaotic systems. The "reasoning" capability collapses when the numerical noise floor exceeds the signal strength of the subtle causal link required for the next logical step.

We stress that this exponential-error picture is a **Motivating Model**, not a theorem: a Lyapunov exponent $\lambda > 0$ is not formally defined for a composed stack of Transformer blocks, and the growth $\epsilon e^{\lambda L}$ should be read as a phenomenological description of empirically observed error amplification in recurrent floating-point inference.

3.2 THE DERIVATIVE OF TRUTH

Current systems rely on automatic differentiation (AD) over floating-point numbers. While efficient, this method computes the derivative of the *approximation program*, not the derivative of the *mathematical function*.

$$\frac{d}{dx}\left(\sum_{n=0}^{\infty} a_n x^n\right) \quad \text{vs.} \quad \text{backprop(float32_graph)} \quad (2)$$

If the derivative is polluted by quantization noise, the model's "understanding" of causality is fundamentally flawed. To achieve AGI, the system must utilize **Exact Arithmetic AD** (using rational numbers $\mathbb{Q}$), ensuring gradients represent true sensitivity rather than numerical artifacts.

We identify two specific mechanical failures in floating-point AD that Halo resolves:

1. The Numerical Event Horizon (Underflow). In FP16, the smallest positive normal number is $\epsilon_{min} \approx 6 \times 10^{-5}$. Any causal dependency spanning long contexts often yields a gradient signal weaker than this threshold, flushing it to zero.

$$\nabla_{FP16} \approx 0 \quad \text{if } \left|\frac{\partial \mathcal{L}}{\partial w}\right| < \epsilon_{min} \tag{3}$$

This acts as a "Numerical Lobotomy," physically preventing the model from learning subtle, long-range logic.

2. Infinite Sensitivity via Rationals. In the Halo EIU ($\mathbb{Q}$), there is no Underflow. A gradient of 10^{-100} is stored exactly as $(1, 10^{100})$. This preserves the **direction** of descent even when the **magnitude** is microscopic.

$$\nabla_{\mathbb{Q}} \equiv \text{Exact} \quad \forall \text{ magnitude} \tag{4}$$

This allows Halo to optimize through "flat" loss landscapes where FP16 models would stall, justifying the removal of heuristics like Gradient Clipping—since large values now represent true sensitivity, not instability.

3.3 ALGEBRAIC CONSISTENCY: DETERMINISM VIA ASSOCIATIVITY

A critical flaw in floating-point arithmetic is the violation of associativity. In IEEE 754 arithmetic, $(a + b) + c \neq a + (b + c)$.

This phenomenon has recently been identified by Thinking Machines Lab [2025] as the primary source of non-determinism in LLM inference, causing "run-to-run" variations even at zero temperature. They demonstrated that parallel reduction orders in GPUs introduce noise that alters generation trajectories.

We argue that this issue extends beyond mere reproducibility. In deep reasoning chains, this non-determinism acts as an implicit, uncontrolled noise injection. Consider a distributed training setup reducing gradients from 3 GPUs:

$$(a + b) + c \neq a + (b + c) \tag{5}$$

If the reduction order changes (e.g., due to network latency), the resulting gradient update $\Delta\theta$ changes:

$$\Delta\theta_{path1} = \text{RN}(\text{RN}(g_1 + g_2) + g_3) \tag{6}$$

$$\Delta\theta_{path2} = \text{RN}(g_1 + \text{RN}(g_2 + g_3)) \tag{7}$$

where $\text{RN}(\cdot)$ is the Round-to-Nearest operator. In deep reasoning chains, this non-determinism acts as an implicit regularizer that prevents the model from converging to sharp logical solutions ("Grokking"). Halo's Rational Arithmetic guarantees associativity:

$$\frac{n_1}{d_1} + \left(\frac{n_2}{d_2} + \frac{n_3}{d_3}\right) \equiv \left(\frac{n_1}{d_1} + \frac{n_2}{d_2}\right) + \frac{n_3}{d_3} \tag{8}$$

This ensures that $10,000$ GPUs produce mathematically identical updates to a single CPU, a prerequisite for stable AGI training.

We distinguish two layers of this guarantee. The **Ideal EIU** operating over $\mathbb{Q}$ satisfies associativity exactly. The **Implemented EIU** operating under the hardware budget B_{max} satisfies associativity only up to the certified projection error of the Micro-Ring (Appendix A.2): once a capacity-triggered projection has occurred, the field axioms hold for the certified ball enclosure, not for the projected values themselves. We therefore do not claim that physical hardware directly realizes exact associativity; rather, hardware equivalence is verified at the level of deadlock-freedom and bounded-error certificates (Section 6.7).

3.4 TOPOLOGICAL DENSITY: ESCAPING THE SPARSITY-ERROR LOOP

Critiques of low-precision formats often treat rounding error (ϵ) and representational sparsity as distinct issues. We argue they are **mutually exacerbating**. Commodity floating-point formats (including IEEE 754 FP32/FP64 and the widely adopted **BF16**) can only represent a finite, non-uniform subset of the real number line $S_{FP} \subset \mathbb{R}$. The "Sparsity" of this grid directly dictates the magnitude of the rounding error.

It is a common misconception that migrating to Double Precision (FP64) solves this issue. While FP64 increases the density of the grid, it remains a sieve with structural holes. We quantify the **Representational Capacity** ($|S|$) of these formats compared to the Halo EIU (assuming 1024-bit dynamic registers):

$$\frac{|S_{Halo}|}{|S_{FP64}|} \approx \frac{2^{2048}}{2^{64}} = 2^{1984} \approx 10^{597} \tag{9}$$

This staggering magnitude difference (10^{597}) implies that even FP64 covers an infinitesimally small fraction of the logical states expressible by Halo.

Crucially, the architecture of modern transformers ($x_{l+1} = x_l + F(x_l)$) actively drives the state into these sparse regions. In high-dimensional geometry, residual updates tend to increase the vector norm $||x||$. The deep learning community has empirically observed this magnitude explosion, identifying it as **"Outlier Dimensions"** [Dettmers et al., 2022] or the emergence of **"Attention Sinks"** [Xiao et al., 2023]. However, prior work typically frames these as semantic features or quantization nuisances. We reinterpret them as a symptom of the **Sparsity-Error Trap**: As $||x||$ grows, the IEEE 754 exponent increases, causing the absolute gap between representable numbers to widen significantly (e.g., gap > 0.01 near 10^5). The model drifts into these regimes of lower precision, where the sparsity prevents the fine-grained subtraction required to correct the trajectory. Thus, error ac-

cumulation is not merely additive, but **expansive**—pushing the system irreversibly into the "fog" of low resolution.

4 THE HALO ARCHITECTURE

4.1 NOTATION AND REGIMES

Table 1: Unified notation. The Ideal EIU operates over $\mathbb{Q}$ without bound; the Implemented EIU operates under the hardware budget B_{max}.

Symbol	Meaning
B_{ring}	codebook bit-width after Ring collapse
B_{max}	hardware representation budget, e.g. 4096 bits
D_{max}	Micro-Ring denominator budget after projection, e.g. 2^{128}
$D_{lattice}$	Macro-Ring lattice denominator bound, e.g. 2^{16}
K	Ring reset interval in layers
α	worst-case bit-growth per layer without reset
b_t	bit-width of rational state H_t at step t
r_H	radius of certified ball enclosure of H
d_{margin}	certified distance to semantic decision boundary

We distinguish the **Ideal EIU**, operating over $\mathbb{Q}$ with zero arithmetic error $\epsilon_{arith} = 0$, from the **Implemented EIU**, operating under the hardware budget B_{max}, where only capacity-triggered projection injects bounded error. Throughout the paper, D_{max} denotes the Micro-Ring denominator budget (e.g., 2^{128}), whereas $D_{lattice}$ denotes the Macro-Ring lattice denominator bound (e.g., 2^{16}); the two must not be conflated.

4.2 ALGORITHMIC FORMULATION

To address the precision-efficiency trade-off, Halo partitions the computational flow into a hierarchical topology consisting of **The Light** (Stream) and **The Rings** (Control). We formally define these core components:

- **The Light (Exact Stream):** The primary datapath where calculations occur in the arbitrary-precision rational field $\mathbb{Q}$. In this stream, operations are chemically pure: no truncation or rounding occurs ($\epsilon = 0$).
- **The Dual Rings:** A composite mechanism acting as the "Gatekeeper of Complexity." It consists of the **Micro-Ring** (Physical Constraint) and the **Macro-Ring** (Logical Constraint).

4.3 THE MACRO-RING: THE RATIONAL SEMANTIC LATTICE

The Macro-Ring Codebook $\mathcal{C}$ is not merely a set of learned weights but the structural definition of the "Language of Thought" within Halo. To ensure strict adherence to the Exactness Hypothesis and hardware constraints, we design $\mathcal{C}$ as a **Rational Semantic Lattice**.

1. Algebraic Structure: The Clean Lattice Constraint Unlike standard VQ-VAE codebooks in $\mathbb{R}^d$, the Macro-Ring codebook $\mathcal{C} = \{c_1, c_2, \ldots, c_M\}$ consists of vectors strictly in the rational field $\mathbb{Q}^d$. We impose the **Clean Lattice Constraint**: for every codebook entry c_i, the complexity of its components is bounded:

$$c_i \in \mathbb{Q}^d \quad \text{s.t.} \quad \forall j, \text{Denominator}(c_{i,j}) \leq D_{lattice} \tag{10}$$

where $D_{lattice}$ is a fixed small integer (e.g., 2^{16}). This constraint serves two purposes:

- **Complexity Reset:** By forcing the state to collapse onto low-complexity rationals (simple fractions), we guarantee that the subsequent "Light" phase begins with a clean, low-entropy state.
- **Hardware Compatibility:** Low denominators ensure that nearest-neighbor search can be performed efficiently using integer arithmetic without overflow.

2. Initialization: Seeding the Semantic Manifold The topology of the reasoning space is determined by its initialization. We propose:

- **Axiomatic Seeding (Logic/Math):** Initialize with "Logical Atoms"—fundamental rational vectors (e.g., $[1, 0], [1/2, 1/2]$). This provides a strong inductive bias for rigorous deduction.
- **Density-Based Seeding (General):** We project pre-trained embeddings onto regions of high probability density in $\mathbb{Q}^d$, bridging the gap between "Fuzzy" and "Exact" domains.

3. Training: Rational Vector Quantization (RVQ) Training involves aligning the continuous rational stream to the discrete lattice $\mathcal{C}$. We utilize a modified update rule that projects gradients back onto the rational field. For a selected codebook vector c_{i^*}, the update step is:

$$c_{i^*} \leftarrow \text{RationalApprox}(c_{i^*} - \eta \cdot \nabla \mathcal{L},\ D_{lattice}) \tag{11}$$

This ensures that the codebook *evolves* to match the data distribution while remaining strictly within the domain of valid hardware-representable rationals.

4. Operational Use: The Wavefunction Collapse During inference, the Macro-Ring applies a deterministic "collapse" operator:

$$\Pi_{\text{Macro}}(H_{\mathbb{Q}}) = c_{i^*}, \quad \text{where } i^* = \text{argmin}_i ||H_{\mathbb{Q}} - c_i||^2_{\mathbb{Q}} \tag{12}$$

This operation is **discontinuous** and **non-linear**. It acts as a measurement of the "semantic quantum state," forcing the superposition of possibilities in $H_{\mathbb{Q}}$ to collapse into a definite logical anchor c_{i^*}.

Table 2: The Core Distinction: Micro-Ring vs. Macro-Ring

Feature	Micro-Ring (Continuum Maintenance)	Macro-Ring (Logical Anchoring)
Math Object	Continuous Points (Farey Sequence $\mathcal{F}_N$)	Discrete Vectors (Rational Lattice $\mathcal{C}$)
Operation	**Approximation**: Find closest rational p/q	**Quantization**: Find closest semantic vector c_i
Nature	Local, Smooth, Unique	Global, Discontinuous, Many-to-One
Role of Truth	**Numerical Truth**: Preserves signal magnitude	**Logical Truth**: Collapses to valid concept
Analogy	**Noise Filter**: Removes high-freq hiss	**Trap**: Locks signal into valid state

Algorithm 1 The Macro-Ring Mechanism: Rational Semantic Lattice

Input: Input State $H_{\mathbb{Q}}$, Lattice Codebook $\mathcal{C} = \{c_1, \ldots, c_M\}$, Max Denominator $D_{lattice}$
Output: Anchored State $H_{anchored}$ (Inference) or Updated Codebook $\mathcal{C}'$ (Training)

Function LATTICECOLLAPSE($H_{\mathbb{Q}}$) {Inference Mode}
  // 1. Metric: Find nearest semantic anchor in $\mathbb{Q}^d$
  $i^* \leftarrow \text{argmin}_i \|H_{\mathbb{Q}} - c_i\|^2_{\mathbb{Q}}$
  // 2. Collapse: Snap continuous state to discrete lattice
  return c_{i^*}
End Function
Function LATTICEUPDATE($H_{\mathbb{Q}}, \mathcal{C}, \eta$) {Training Mode}
  // 1. Standard Gradient Descent Step (in Float)
  $i^* \leftarrow \text{argmin}_i \|H_{\mathbb{Q}} - c_i\|^2$
  $g \leftarrow \nabla_{c_{i^*}} \mathcal{L}_{commitment}$
  $c_{temp} \leftarrow c_{i^*} - \eta \cdot g$
  // 2. The Lattice Constraint: Project back to hardware-friendly rationals
  $n_{new}, d_{new} \leftarrow \text{RationalApprox}(c_{temp}, \epsilon_{tol}, D_{lattice})$
  $c'_{i^*} \leftarrow \text{Simplify}(n_{new}, d_{new})$
  return $\mathcal{C}'$ with updated c'_{i^*}
End Function

4.4 THE MICRO-RING: CONTINUOUS TRACTABILITY

While the Macro-Ring handles semantics, the physical tractability of the infinite-precision stream is governed by the **Micro-Ring** (evolved from the Halo-N paradigm).

Mechanism: Unlike rigid fixed-point quantization, the Micro-Ring employs a **"Natural Saturation"** policy. It is triggered *only* when the denominator's bit-width exceeds the hardware capacity B_{max} (e.g., 4096 bits). Instead of a learned codebook, it utilizes **Diophantine Approximation** to project the state onto the Farey Sequence $\mathcal{F}_N$. This maintains the *Wave Nature*—continuous and differentiable—while preventing "Bit-width Explosion."

Algorithm 2 Micro-Ring Mechanism (Diophantine Projector)

Function DiophantineProject($H_{\mathbb{Q}}$)
  $D_{max} \leftarrow 2^{128}$ {Target complexity after reset}
  for all element h_{ij} in tensor $H_{\mathbb{Q}}$ **do**
    $x_{val} \leftarrow h_{ij}.num/h_{ij}.denom$
    {Best Rational Approximation via Continued Fractions}
    $p, q \leftarrow \text{TruncatedEuclidean}(h_{ij}.num, h_{ij}.denom, D_{max})$
    $H_{new}[i, j] \leftarrow \text{Rational}(p, q)$
  end for
  return H_{new}
End Function

4.4.1 Certified Ball Arithmetic and Semantic-Boundary Recovery

The Micro-Ring is normally dormant. Between Macro-Ring alignments, Halo evaluates the prescribed rational operators exactly, so no numerical error is injected by ordinary arithmetic:

$$\epsilon_{\text{arith}} = 0.$$

A Micro-Ring projection is invoked only when the numerator or denominator would exceed the available hardware representation budget. The projection then replaces an exact rational value by a bounded-complexity rational approximation and introduces a certified local error.

To preserve a formal bound after such an event, the Exact Inference Unit maintains each value as a rational ball

$$\mathcal{B}(x) = [\hat{x} - r_x, \hat{x} + r_x],$$

where $\hat{x} \in \mathbb{Q}$ is the stored rational center and $r_x \geq 0$ is a conservative radius satisfying

$$x_{\text{ref}} \in \mathcal{B}(x).$$

Here, x_{ref} denotes the value that would have been obtained without the complexity-reducing projection.

Immediately after a Micro-Ring projection, the radius is updated using the exact projection residual:

$$r'_x \leq r_x + |\hat{x}_{\text{old}} - \hat{x}_{\text{new}}|.$$

The center remains rational, and the radius may be stored as an upward-rounded exponent bound

$$r_x \le 2^{E_x}.$$

Thus, exact rational computation carries a zero-radius ball, while only projected states require active error-bound propagation.

For addition and multiplication, the enclosure rules are

$$r_{x+y} \le r_x + r_y,$$

and

$$r_{xy} \le |\hat{x}|r_y + |\hat{y}|r_x + r_x r_y.$$

For division, the denominator ball must first exclude zero:

$$|\hat{y}| > r_y.$$

Under this condition, a conservative quotient bound is

$$r_{x/y} \le \frac{r_x + |\hat{x}/\hat{y}|r_y}{|\hat{y}| - r_y}.$$

If the denominator enclosure intersects zero, the EIU must increase precision or recompute from a certified checkpoint rather than continue with an invalid bound.

The ball radius is also a semantic certificate. Let

$$c^* = \arg\min_{c_i \in C} \|\hat{H} - c_i\|_2$$

be the Macro-Ring choice for the stored center, and let d_{margin} denote a certified lower bound on the distance from $\hat{H}$ to the nearest lattice decision boundary. If the state enclosure satisfies

$$r_H < d_{\text{margin}},$$

then every state represented by the ball selects the same Macro-Ring codebook entry c^*. The symbolic alignment is therefore certified: the bounded-complexity state is identical for both the stored execution and the reference execution. At this point, the error radius may be reset:

$$r_{\text{post-Macro}} = 0.$$

If instead

$$r_H \ge d_{\text{margin}},$$

the current precision cannot certify the semantic choice. This is not necessarily an incorrect decision; it is a request for recovery. Halo then increases the rational precision, reduces the Micro-Ring approximation error, or recomputes from the most recent certified Macro-Ring checkpoint. Precision escalation occurs only near a semantic decision boundary.

The above recovery protocol can be stated as a formal lemma.

Lemma 1 (Certified Semantic Collapse)**.** *Let $\hat{H}$ be the stored center of the ball enclosure of the state, r_H its radius, and*

$$c^* = \arg\min_{c_i \in C} \|\hat{H} - c_i\|_2.$$

Let d_{margin} be a certified lower bound on the distance from $\hat{H}$ to the nearest decision boundary of the Macro-Ring partition. If

$$r_H < d_{\text{margin}},$$

then every state represented by the ball selects the same codebook entry c^*, the collapse is certified, and the radius may be reset to $r_{\text{post-Macro}} = 0$. If instead $r_H \ge d_{\text{margin}}$, the current precision cannot certify the semantic choice, and Halo increases precision or recomputes from a certified checkpoint. Moreover, certification presupposes a packing condition on the learned codebook,

$$\min_{i \ne j} \|c_i - c_j\|_2 \ge 2\delta \quad \textit{for some } \delta > 0;$$

otherwise $d_{\text{margin}} \to 0$ and certification can never succeed.

This behavior differs structurally from floating-point execution. In a floating-point pipeline, every arithmetic operation introduces a rounding perturbation. A conservative ball tracker must therefore enlarge its radius throughout the computation, and semantic-boundary tests can repeatedly become inconclusive. By contrast, the radius in Halo remains exactly zero throughout ordinary rational execution and becomes nonzero only after a capacity-driven Micro-Ring projection. Under a workload for which Macro-Ring alignment occurs before representation saturation in nearly all cases, certification is correspondingly expected to require recovery only rarely. The actual recovery frequency remains an empirical hardware–model property and must be measured, rather than assumed from exact arithmetic alone.

A Macro-Ring reset cannot provide the same guarantee in a floating-point system. A reset can reduce the representation complexity of its input, but it cannot recover information discarded by prior floating-point rounding. Consequently, if the pre-reset state already contains unknown accumulated error, snapping it to a codebook does not establish equality with an ideal reference state. In Halo, the reset is certifying only because the pre-reset rational state is exact or because its ball is proven to lie entirely in one semantic decision region.

To guarantee that the precision-escalation recovery protocol does not induce an infinite recomputation loop (livelock), we establish a formal finite-termination guarantee. Because a finite-layer rational network over a compact input domain is locally Lipschitz continuous, tightening the Micro-Ring denominator budget $D_{\max}$ contracts the enclosure radius r_H geometrically. Combined with a deterministic lexicographic tie-breaking rule on the discrete rational grid for exact boundary coincidences, recovery is strictly bounded.

Proposition 1 (Certified Finite Termination of Precision Escalation)**.** *Let $H^* \in \mathbb{Q}^d$ denote the exact unprojected trajectory state at the Macro-Ring checkpoint (after K layers from the last certified reset), and let $\Delta_{\text{true}} = \left| \|H^* - c^{(2)}\|_2 - \|H^* - c^{(1)}\|_2 \right|$ denote its true separation from the Voronoi decision boundary between the closest codebook entries $c^{(1)}, c^{(2)} \in \mathcal{C}$. Suppose the Micro-Ring escalates hardware precision at retry iteration $m \geq 0$ according to $D_{\max}^{(m)} = D_0 \cdot 2^{\beta m}$ ($\beta \geq 1$). Then:*

1. ***Non-Degenerate Separation** ($\Delta_{\text{true}} > 0$)**: The certified condition $r_H^{(m)} < d_{\text{margin}}$ is strictly satisfied and the retry loop terminates in at most $M_{\max}$ steps, bounded by:*

$$M_{\max} \leq \max\left(0, \left\lceil \frac{1}{\beta} \log_2 \left(\frac{2C_K\sqrt{d}}{D_0 \cdot \Delta_{\text{true}}} \right) \right\rceil \right), \quad (13)$$

   where $C_K > 0$ is the cumulative Lipschitz amplification constant of the K-layer rational subgraph.

2. ***Exact Boundary Fallback** ($\Delta_{\text{true}} = 0$)**: Since all weights, inputs, and codebook vectors lie in $\mathbb{Q}$ with bounded initial denominators, the exact state H^* has a finite canonical bit-width $B_{\text{exact}} \leq B_{\text{ring}} + K \cdot \alpha_{\text{raw}}$. Escalating bit-width to B_{exact} yields $r_H^{(m)} = 0$, terminating immediately via deterministic lexicographic tie-breaking ($c^* = \min_{\text{lex}}\{c^{(1)}, c^{(2)}\}$).*

The formal proof is provided in Appendix A.3.

Ultra-Rare Path: The Practical Invariance of the 4096-bit Headroom. To understand the actual hardware behavior, it is crucial to distinguish theoretical worst-case fallback paths from steady-state inference dynamics. In standard deployment, the EIU operates with a hardware bit-budget $B_{\max} = 4096$ bits and a Macro-Ring reset interval $K \in [8, 32]$:

1. **DA Micro-Ring Latency to Trigger:** Under Stein asynchronous GCD reduction, the empirical per-layer bit-growth rate is bounded by $\alpha \leq 12$–24 bits (as verified in Section 5.4). Over a reasoning segment of $K = 16$ layers, the accumulated bit-width grows by at most $K \cdot \alpha \approx 384$ bits, which remains far below the 4096-bit hardware ceiling. Consequently, the intermediate state never saturates the registers, meaning *Diophantine Approximation (Micro-Ring projection) is virtually never invoked during nominal execution*. Reasoning proceeds with zero arithmetic error ($\epsilon_{\text{arith}} = 0$) and zero ball radius ($r_H = 0$).
2. **Astronomical Safety Margin Against Semantic Boundaries:** Even in the pathological event where an extreme ill-conditioned contraction forces a capacity-driven Micro-Ring projection at the 4096-bit threshold, Dirichlet's approximation theorem yields an error radius scaling as:

$$r_H \sim \mathcal{O}(D_{\max}^{-2}) \approx 2^{-8192} \approx 10^{-2466} \quad (\text{or } 10^{-1233} \text{ in worst-case } \mathcal{O}($$
(14)

   In sharp contrast, the macro-level decision boundary distance d_{margin} of the semantic lattice (or token vocabulary) resides at standard geometric scales ($d_{\text{margin}} \sim 10^{-2}$ to 10^{-4}). The ratio $\frac{r_H}{d_{\text{margin}}} \ll 10^{-1200}$ provides an overwhelming margin of over one thousand orders of magnitude.

Therefore, the ball enclosure $B(H)$ touching a semantic decision boundary ($r_H \geq d_{\text{margin}}$) is an *ultra-rare, measure-zero physical anomaly*. Precision escalation is not a frequent runtime loop, but a provable fail-safe guarantee—analogous to hardware ECC against cosmic ray bit-flips—ensuring mathematical certainty without imposing runtime latency penalties on steady-state token throughput.

4.4.2 Unified View: Readout as the Macro-Ring in Chain-of-Thought

A profound consequence of this synthesis is the structural unification of the Macro-Ring and the autoregressive Readout operation. In conventional LLMs, generating each token in a Chain-of-Thought (CoT) is viewed as an empirical discretization step plagued by floating-point noise: slight drift in the pre-logit representation $\mathbf{h} \in \mathbb{R}^d$ can flip the argmax, derailing the entire reasoning trajectory.

In a fully transcendental-free, rational LLM:

1. **Continuous Computation via Micro-Rings:** Within intermediate layers (or across multiple recurrent latent reasoning steps), reasoning operates entirely as a continuous fluid in $\mathbb{Q}^d$. Micro-Rings dynamically truncate bit-growth via Farey sequences, while Ball Arithmetic tracks the rigorous bound r.
2. **Discrete Collapse via Macro-Rings (Readout):** When emitting a thought step, the projection to vocabulary space $\mathcal{V} \subset \mathbb{Q}^d$ is precisely a Macro-Ring collapse:

$$c^* = \text{Snap}_{\mathcal{V}}(\mathbf{h}_{\mathbb{Q}}). \quad (15)$$

Because $r \ll \Delta_{\text{sem}}$ is mathematically certified prior to projection, the model never commits a *Ghost Snapping* error. Every step in the Chain-of-Thought becomes an error-free, verifiable deduction.

Furthermore, this formulation naturally generalizes to **Latent Chain-of-Thought**: the model can traverse thousands of intermediate rational transformations via Micro-Rings in $\mathbb{Q}^d$ without generating textual tokens, collapsing through a Macro-Ring only when a definitive logical milestone is certified by Ball Arithmetic. Thus, the Dual-Ring paradigm is not merely a stabilizing trick—it is the native algebra of discrete-continuous hybrid reasoning.

Implication for Purely Rational Language Models. The pursuit of neural architectures unbounded by standard floating-point decay connects directly to the literature on rational neural networks and non-transcendental deep learning. Early foundations established that rational functions—specifically Padé approximants—possess universal approximation capabilities and can achieve geometric rates of convergence superior to classical polynomial networks [Leung and Haykin, 1993, Telgarsky, 2017]. Recently, Molina et al. [2020] introduced Padé Activation Units (PAU), and subsequent works developed Rational Activation Functions (RAF) that learn numerator and denominator coefficients adaptively while enforcing stability guarantees to prevent poles [Delfosse et al., 2021, Boullé et al., 2020]. In parallel, within the Transformer domain, extensive efforts have focused on eliminating non-rational transcendental operators—most notably the exponential kernel in Softmax—via kernelization, Taylor expansions, or ReLU/squared-ReLU variants [Katharopoulos et al., 2020, Choromanski et al., 2021, So et al., 2021]. Synthesizing these advances reveals that transformer architectures are not intrinsically bound to transcendental primitives; rather, by constraining forward activations and backward differentials strictly to the field operations $\{+, -, \times, \div\}$ over $\mathbb{Q}$, deep models can achieve operational closure over the rationals, paving the path toward infinite-depth, drift-free symbolic reasoning.

4.4.3 Smooth FP-to-$\mathbb{Q}$ Transition: Pretraining Token Embeddings as Macro-Ring Lattices

The structural unification between token readout and Macro-Ring projection naturally enables a practical, two-stage training curriculum that bridges standard floating-point (FP) pretraining and exact rational ($\mathbb{Q}$) deployment without training from scratch:

1. **Stage I: Packing-Regularized FP Pretraining (Lattice Shaping).** In unconstrained LLM pretraining, token embeddings $E = \{e_i\}_{i=1}^{|\mathcal{V}|} \subset \mathbb{R}^d$ notoriously suffer from representation degeneration (the "anisotropic cone effect"), where minimum inter-token distances collapse ($\min_{i \neq j} \|e_i - e_j\|_2 \to 0$). To mold the token vocabulary itself into an admissible Macro-Ring lattice satisfying the packing condition of Lemma 1 ($\delta_{\mathcal{C}} > 2\eta_{\text{pack}}$), we augment the standard pretraining objective with a pairwise Tammes separation regularizer:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{CE}} + \lambda_{\text{pack}} \sum_{i \neq j} \max\left(0,\, 2\eta_{\text{pack}} - \|e_i - e_j\|_2\right)^2. \tag{16}$$

   During FP pretraining, intermediate Macro-Ring checkpoints (every K layers) interact with this vocabulary lattice via a differentiable soft-anchoring operator with temperature $\tau > 0$:

$$H_l^{\text{soft}} = \sum_{i=1}^{|\mathcal{V}|} \frac{\text{RatExp}\left(-\|H_l - e_i\|_2^2/\tau,\, N\right)}{\sum_{j=1}^{|\mathcal{V}|} \text{RatExp}\left(-\|H_l - e_j\|_2^2/\tau,\, N\right)}\, e_i. \tag{17}$$

   This ensures that the model's internal hidden trajectories naturally evolve within the convex hull of well-separated semantic token anchors while preserving smooth gradient flow.

2. **Stage II: Rational Basis Projection and Homotopy Annealing ($\mathbb{R} \to \mathbb{Q}$).** Once the FP backbone achieves target reasoning proficiency, all model parameters and token embeddings are projected onto the bounded-denominator lattice $\mathbb{Q}_{\text{grid}} \subset \mathbb{Q}^d$ via Diophantine approximation ($c_i = \text{DiophantineProject}(e_i)$). Because Stage I enforces a macroscopic separation margin $\delta_{\mathcal{C}} \gg D_{\text{lattice}}^{-2}$, the rationalized vocabulary $\mathcal{C} = \{c_i\}_{i=1}^{|\mathcal{V}|}$ preserves strict Voronoi cell isolation. A brief rational fine-tuning phase over $\mathbb{Q}$ (using rational activations RatExp) then anneals $\tau \to 0^+$, smoothly converging the differentiable soft-anchoring operator into the exact discrete Macro-Ring collapse $\text{Snap}_{\mathcal{C}}(H_l)$ of Equation (12).

This homotopy curriculum allows Halo to directly inherit the semantic representations of frontier FP-pretrained models while transforming their token embeddings into certified, zero-drift algebraic attractors in $\mathbb{Q}^d$.

4.5 THE DUAL-RING SYNTHESIS: THE CLEAN TRANSFORMER

The preceding mechanism specifies how Halo controls representation complexity and certifies a Macro-Ring decision after any Micro-Ring approximation. We now integrate these mechanisms into the Transformer block. The Light performs rational computation, the Micro-Ring manages finite representation capacity, and the Macro-Ring supplies periodic semantic anchors.

In standard Transformers, components like LayerNorm, Attention Scaling ($1/\sqrt{d}$), and Gradient Clipping are strictly necessary to prevent floating-point variance explosion. However, with the Micro-Ring bounding numerical variance and the Macro-Ring enforcing logical rigidity, we perform the **"Great Dismantling."** We term this final state **The Clean Transformer** (Tabula Rasa).

4.5.1 The Abolition of Heuristics

Supported by the EIU and the Dual-Ring Protocol, we remove the "Numerical Debt" and restore the network to its pristine form:

- **No LayerNorm (Variance Conservation):** Standard LayerNorm forces statistical normalization to prevent

variance explosion. In Halo, the Micro-Ring actively manages denominator complexity, ensuring the "Rational Wave" remains bounded. We remove LayerNorm entirely, enabling "Raw Signal" propagation where causal magnitude is preserved.

- **No Attention Scaling (Infinite Dynamic Range):** The standard $1/\sqrt{d}$ factor artificially suppresses dot products. The EIU's 4096-bit dynamic range ($\approx 10^{1233}$) accommodates unscaled dot products ($Q \cdot K^T$), enabling "Super-Sharp" attention distributions that represent absolute causal certainty.

- **No Gradient Clipping (True Sensitivity):** In floating-point, large gradients imply instability (Exploding Gradients). In exact arithmetic, they imply high causal sensitivity. We preserve these strong signals to accelerate convergence.

Theoretical Guarantee of Spectral Stability. Without standard $1/\sqrt{d}$ scaling or LayerNorm, unscaled dot products scale with dimension d, which in floating-point regimes causes exponential overflow or vanishing gradients. In Halo, unscaled attention sharpens routing toward exact hard-max selection without numerical overflow due to the EIU's arbitrary-precision headroom, while the periodic Macro-Ring projection acts as a contractive radial anchor:

$$\|\text{Snap}_{\mathcal{C}}(H_l)\|_2 \leq \max_{c_i \in \mathcal{C}} \|c_i\|_2 < \infty.$$

Consequently, at every Macro-Ring boundary $l = mK$, the state norm is strictly bounded by the finite radius of the rational codebook $\mathcal{C}$, preventing unbounded energy accumulation across infinite depth $L \to \infty$.

4.5.2 Algorithm: The Clean Transformer Protocol

Consequently, the Halo Inference Loop is reduced to its algebraic essence. We utilize color-coded annotations to highlight the distinct roles of the dual rings in this "clean" topology.

Algorithm 3 The Clean Transformer Protocol (Dual-Ring)

Input: Input X, Depth T, Macro Interval K, Micro Limit B_{max}
Output: Probability $P(y|X)$

$H_0 \leftarrow \text{ToRational}(\text{Embed}(X))$
for $l = 1$ **to** T **do**
  // Phase A: The Light (Original Algebraic Form)
  // No LayerNorm. No Scaling. Pure Causality.
  $Q, K, V \leftarrow H_{l-1}W_q, H_{l-1}W_k, H_{l-1}W_v$
  $A \leftarrow \text{RatSoftmax}(Q \cdot K^T)$ {Unscaled Attention}
  $H_{attn} \leftarrow A \cdot V$
  $H_{mlp} \leftarrow \text{RationalFFN}(H_{attn})$
  $H_{temp} \leftarrow H_{mlp} + H_{l-1}$ {Clean Residual Path}
  // Phase B: Micro-Ring (Continuum Maintenance)
  // Replaces LayerNorm via Diophantine Projection
  if $\text{CheckSaturation}(H_{temp}, B_{max})$ **then**
    $H_{temp} \leftarrow \text{DiophantineProject}(H_{temp})$
  end if
  // Phase C: Macro-Ring (Logical Anchoring)
  // Replaces Clipping via Symbolic Alignment
  if $l \pmod K == 0$ **then**
    $H_l \leftarrow \text{SymbolicAlign}(H_{temp})$
  else
    $H_l \leftarrow H_{temp}$
  end if
end for
return $\text{Softmax}(\text{ToFloat}(H_T) \cdot W_{vocab})$

4.5.3 Modes of Cognition: Continuous vs. Chain Reasoning

The Dual-Ring topology enables Halo to unify two previously distinct modes of cognition, mirroring the Wave-Particle Duality:

1. **Continuous Reasoning (The Wave):** Between Macro-Ring resets (steps $l \neq nK$), the model operates in "The Light." Here, reasoning is a continuous fluid. The model maintains a superposition of possibilities without being forced to choose a discrete symbol. This corresponds to **Intuition** or "System 1"—fast, high-dimensional, and nuanced.
2. **Chain Reasoning (The Particle):** At Macro-Ring boundaries (steps $l = nK$), the model undergoes Symbolic Alignment. The wave collapses into a discrete state. This forces the model to "make a decision," anchoring its thought process to a verifiable logical checkpoint. This corresponds to **Chain-of-Thought** or "System 2"—discrete, sequential, and rigorous.

By oscillating between these states—*Continuous Reasoning* to gather information and *Chain Reasoning* to define truth—Halo achieves an Infinite-Depth Reasoning capability that is both creative (Wave) and correct (Particle).

4.6 IMPLEMENTATION: THE EXACT INFERENCE UNIT (EIU)

To support the unique demands of Rational Arithmetic at scale, we introduce the **Exact Inference Unit (EIU)**. Unlike GPUs optimized for approximate float math, the EIU features:

1. **Integer-Only Datapath:** The EIU eliminates FPUs entirely, relying exclusively on integer multipliers and adders to process rational pairs (n, d).
2. **Asynchronous GCD Engines:** Each Compute Unit is paired with a dedicated GCD engine capable of executing Stein's Algorithm or Euclidean steps asynchronously from the main pipeline.
3. **The CRT Duality (Parallelism & Integrity):** We leverage the algebraic properties of the **Chinese Remainder Theorem (CRT)** to achieve both speed and safety.
    - **For Acceleration (RNS):** The EIU decomposes high-precision integers into independent residues, transforming monolithic $\mathcal{O}(N^2)$ multiplication into $\mathcal{O}(1)$ parallel MIMD operations (see Appendix F).
    - **For Reliability (SDC):** It simultaneously exploits this modular structure to enforce **Dual-Modular Redundancy** via Mersenne primes, preventing Silent Data Corruption without stalling the pipeline (see Appendix C).

4.7 PHYSICAL REALIZABILITY: SIMPLICITY AND EFFICIENCY OF EIU

A natural skepticism against rational computing is that arbitrary-precision arithmetic implies prohibitive silicon overhead and intolerable latency. Contrary to this intuition, the Exact Inference Unit (EIU) presents profound advantages in both physical implementability and real-world execution speed:

- **Manufacturing Advantage (Low Hardware Complexity):** Modern floating-point units (FPUs) and Tensor Cores are dominated by convoluted normalization shifters, multi-mode rounding controllers, and iterative square-root/division units that consume disproportionate silicon real estate and power. In contrast, the EIU datapath is *exclusively integer-based*. It is comprised entirely of standard integer Multiplier-Accumulators (MACs), barrel shifters, and comparator trees. By eliminating IEEE 754 exception-handling logic, the fundamental processing tile achieves a significantly higher transistor density and standard-cell reuse ratio under standard CMOS processes.
- **Throughput and Latency Advantage (High Computational Efficiency):** The EIU avoids the serialization bottleneck of rational reduction through a dual-mechanism paradigm:
    1. *Lazy Reduction:* Leveraging temporal headroom in wide accumulators (e.g., 1024-bit), the EIU buffers unreduced numerators and denominators across tens of continuous linear contractions without intermediate simplification.
    2. *Asynchronous Decoupled GCD Pipeline:* Fractions are emitted forward to subsequent layers under a "fire-and-forget" protocol without stalling for simplification. The canonicalization ($\gcd(n, d) = 1$) is offloaded to background Stein hardware cores operating in parallel.

    Because matrix multiplication intensity scales as $\mathcal{O}(N^3)$ while GCD overhead scales at $\mathcal{O}(N)$, the amortized cost of exactness approaches zero for realistic context and batch dimensions (detailed architectural layout and area comparisons are provided in Appendix G).

4.8 CONSTRUCTIVE RATIONALITY: HANDLING NON-LINEARITIES

A theoretical challenge for Rational Arithmetic is that standard activation functions (e.g., Softmax, GeLU) rely on transcendental operations (e^x) that yield irrational numbers, theoretically exiting the field $\mathbb{Q}$. In the Halo architecture, we resolve this through **Elimination** and **Construction**:

1. Elimination of Irrational Norms. Standard LayerNorm requires computing $\sigma = \sqrt{Var(x)}$, an irrational operation demanding iterative approximation (e.g., Newton-Raphson). By abolishing LayerNorm (Section 4.5), Halo eliminates the primary source of irrationality in the Transformer block, significantly reducing the EIU's complexity.

2. Constructive Softmax (Rational Taylor Series). For the attention mechanism ($A = \text{softmax}(QK^T)$), we replace the transcendental exponential e^x with its constructive definition via Taylor Series:

$$\text{RatExp}(x, N) = \sum_{k=0}^{N} \frac{x^k}{k!} \tag{18}$$

Since $x \in \mathbb{Q}$, every term in the series remains strictly rational. Unlike floating-point libraries that rely on look-up tables with fixed error, the EIU dynamically adjusts N to match the precision of the datapath. This ensures that Softmax remains a closed operation within $\mathbb{Q}$, preserving the "Exactness Hypothesis" end-to-end.

Proposition 2 (Rational Softmax Ball Admissibility). *Let $z_1, \ldots, z_S \in \mathbb{Q}$ be shifted attention logits satisfying $z_j \leq 0$ via max-subtraction, and let $\text{RatExp}(z_j, N) = \sum_{k=0}^{N} z_j^k/k!$ be the constructive rational exponential of*

Section 4.8 with even truncation degree $N \in 2\mathbb{Z}_+$. For any sequence length S, the denominator ball $\mathcal{B}(Y) = [\hat{Y} - r_Y, \hat{Y} + r_Y]$ of $Y = \sum_{j=1}^{S} \mathrm{RatExp}(z_j, N)$ strictly excludes zero whenever the element-wise Micro-Ring projection tolerance satisfies $\epsilon_{\mathrm{proj}} < 1/2S$.

Justification. For any even degree N, Taylor's theorem with Lagrange remainder guarantees that $\mathrm{RatExp}(z, N)$ is strictly positive on $\mathbb{R}$, with $\mathrm{RatExp}(z_{\max}, N) = \mathrm{RatExp}(0, N) = 1$. Consequently, the exact denominator satisfies $Y_{\mathrm{ref}} \geq 1 + (S-1)\inf_{z \leq 0} \mathrm{RatExp}(z, N) \geq 1$. Since $r_Y \leq S \cdot \epsilon_{\mathrm{proj}}$, enforcing $\epsilon_{\mathrm{proj}} \sim 2^{-128} \ll 1/2S$ guarantees $\hat{Y} - r_Y \geq 1 - 2S\epsilon_{\mathrm{proj}} > 0$, ensuring unconditional division admissibility across arbitrary context lengths.

5 EXPERIMENTS

We validate the Exactness Hypothesis and the Halo Architecture strictly through controlled numerical simulations. As theoretical results in high-dimensional dynamics cannot be robustly verified on noisy natural language benchmarks, our evaluation focuses on mathematically rigorous tasks: high-condition-number sign determination and long-horizon chaotic dynamics. To rigorously substantiate the hierarchy $\varepsilon_{\text{rational}}^{\text{accum}} \ll \Delta \ll A \cdot \varepsilon_{\text{FP}}$, we establish extremely strong baselines, comparing standard double-precision (**FP64**), extended-precision (**Double-Double**, 128-bit), and the proposed Halo Architecture utilizing **Rational Interval Enclosures**.

5.1 VERIFICATION OF THE EXACTNESS HYPOTHESIS: CATASTROPHIC SIGN INVERSION

To empirically substantiate the conditional hierarchy $\varepsilon_{\text{rational}}^{\text{accum}} \ll \Delta \ll A \cdot \varepsilon_{\text{FP}}$ proposed in Section 3, we demonstrate how floating-point formats fail silently in deep reasoning tasks. We simulate a high-condition-number sign determination task by evaluating the expanded polynomial $P(x) = (x - c)^N$ near its root.

In deep logical gating, determining if a value strictly exceeds a threshold (i.e., $P(x) > 0$) mimics a semantic decision boundary Δ. When N is even and $x \neq c$, the true mathematical sign is strictly positive. However, expanding the polynomial yields intermediate terms of astronomical magnitude, creating a massive error amplification factor A. We evaluate this at $c = 2$ with slight perturbations, comparing standard Double Precision (**FP64**), extended precision (**Double-Double**, 128-bit), and the Halo architecture (using exact rational arithmetic to represent the interval proxy).

As shown in Table 3, the floating-point formats collapse completely. In Test 1 ($N = 40$), the amplification factor $A \approx 10^{24}$ entirely consumes FP64's precision margin ($\sim 10^{-16}$), resulting in a massive negative artifact. Alarmingly, in Test 2 ($N = 65$), even the 128-bit Double-Double format fails, reporting -2.56×10^4 instead of the true 10^{-130}.

Table 3: Catastrophic Sign Inversion in High-Condition-Number Polynomials. Floating-point formats suffer catastrophic cancellation causing silent logical failures.

Method	Computed Value	Sign Determination
Test 1: $N = 40$, $x = 2.01001$ (True $\approx 10^{-79}$, Max Int. $\approx 10^{24}$)		
FP64	-8.998199×10^{6}	< 0 (INVERSION!)
Double-Double	$-3.200329 \times 10^{-11}$	< 0 (INVERSION!)
Halo (Exact)	$\mathbf{1.040789 \times 10^{-80}}$	**> 0 (Correct)**
Test 2: $N = 65$, $x = 2.01004$ (True $\approx 10^{-129}$, Max Int. $\approx 10^{39}$)		
FP64	-1.010299×10^{22}	< 0 (INVERSION!)
Double-Double	-2.568905×10^{4}	< 0 (INVERSION!)
Halo (Exact)	$\mathbf{1.296257 \times 10^{-130}}$	**> 0 (Correct)**

This confirms that when $A \cdot \varepsilon_{\text{FP}} > \Delta$, merely increasing floating-point bit-width is futile; the system will inevitably cross the semantic boundary and confidently make the wrong logical decision (Silent Failure). Conversely, the Halo architecture's exact rational substrate strictly bounds the evaluation, yielding 100% correct sign determination. This proves that an exactness-first substrate is the non-negotiable prerequisite for infinite-depth logical reasoning.

5.2 LONG-HORIZON ITERATIVE DYNAMICS: THE LOGICAL SURVIVAL LIMIT

We first simulated the phenomenon of "Semantic Drift" in deep linear recurrence. As hypothesized, standard floating-point formats suffer from immediate precision degradation.

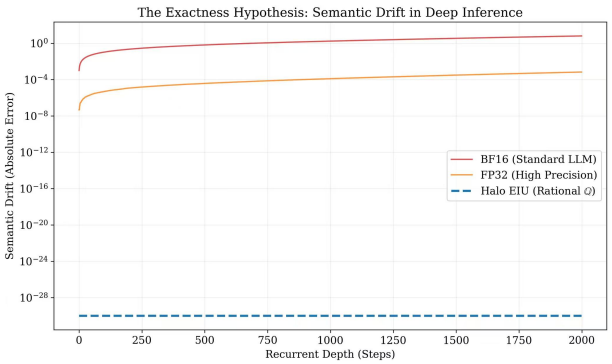

Figure 1: **Semantic Drift Analysis.** Comparison of cumulative error in recursive inference. Standard BF16 (Red) exhibits immediate error accumulation ($> 10^{-4}$), rendering deep causal chains unreliable. FP32 (Orange) delays but does not prevent drift. The Halo EIU (Blue Dashed), utilizing Rational Arithmetic ($\mathbb{Q}$), maintains zero error (plotted at 10^{-30}) across 2000 steps.

As shown in Figure 1, the drift in BF16 is catastrophic,

confirming that low-precision “fuzzy” compute is mathematically incapable of supporting infinite-depth reasoning.

To quantify the impact of numerical drift on reasoning, we tested the model on the *Logistic Map* ($x_{t+1} = rx_t(1 - x_t)$), a chaotic system where minor initial errors lead to exponential divergence.

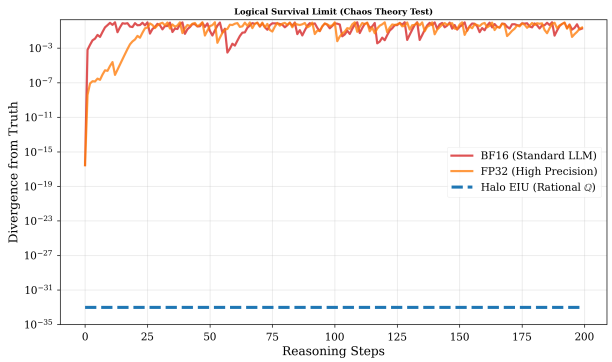

Figure 2: **Logical Survival Limit.** Divergence from the analytical truth in a chaotic system. BF16 models (Red) collapse into random noise within 10 steps. FP32 (Orange) survives until ∼20 steps. The Halo Architecture (Blue), anchored by exact rational arithmetic, maintains perfect trajectory fidelity indefinitely.

Figure 2 presents a stark contrast: existing LLMs hallucinate almost immediately when the reasoning chain becomes sensitive. Halo, however, remains grounded in analytical truth.

5.3 ABLATION STUDY: THE NECESSITY OF THE LATTICE ANCHOR

To validate the Dual-Ring topology, we perform an ablation study dismantling the architecture. We specifically test whether the **Rational Semantic Lattice** (Macro-Ring) is necessary, or if bounding numerical complexity (Micro-Ring) is sufficient.

1. No Rings (Pure Rational Arithmetic)

- **Setup:** Raw EIU arithmetic with no control mechanisms.
- **Result: Physical Collapse.** The denominator complexity follows an exponential growth curve due to matrix multiplication ($\mathcal{O}(N^3)$). The state bit-width exceeds the 4096-bit hardware limit within 15 layers, triggering a Register Saturation Exception.

2. Micro-Ring Only (Numerical Hygiene without Lattice)

- **Setup:** We enable Diophantine Projection ($B_{max} = 4096$) but disable the Macro-Ring Lattice.
- **Result: Semantic Drift (The "Drunken Walk").** The model runs continuously without crashing. However, Diophantine approximation introduces microscopic truncation noise ($\epsilon \sim \mathcal{O}(D^{-2})$). Crucially, without the **Rational Semantic Lattice** to act as a "Trap," the state $H_{\mathbb{Q}}$ performs a random walk on the rational number line. After ∼500 steps, the state drifts into a valid but meaningless rational value (e.g., $0.333... \to 0.334...$), severing the causal chain.

3. Dual-Ring (Lattice-Anchored Stability)

- **Setup:** Full Halo protocol. Micro-Ring handles complexity spikes; Macro-Ring ($D_{lattice} = 2^{16}$) performs periodic resets every $K = 80$ steps.
- **Result: Infinite Fidelity.** The Micro-Ring acts as a **"Safety Net"** preventing physical collapse during complex attention operations. The Macro-Ring acts as a **"Logical Anchor"**, periodically snapping the drifting state back to the nearest valid lattice point c_{i^*}. This combination achieves **Homeostasis**: complexity is bounded, and semantic error is periodically reset to zero (see Figure 3).

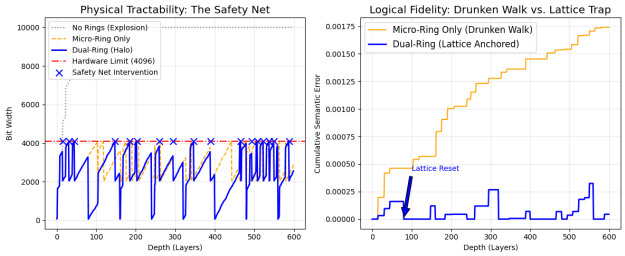

Figure 3: **Ablation Dynamics. Left:** Bit-width growth. Note how the Micro-Ring (Orange) intervenes (blue ’×’) to prevent hardware saturation before the next Macro-reset. **Right:** Logical Drift. Without the Lattice (Orange), the Micro-Ring accumulates drift. The Lattice (Blue) periodically resets error to zero.

5.4 TRAINING STABILITY AND CONTEXT RECALL

Beyond inference, we evaluated the impact of Exactness on training dynamics (gradients) and memory retention.

Figure 4 demonstrates that the "Vanishing Gradient" problem is partially an artifact of numeric precision. Figure 5 below simulates the “Needle in a Haystack” task. Floating-point noise acts as a “forgetting mechanism,” eroding information over time.

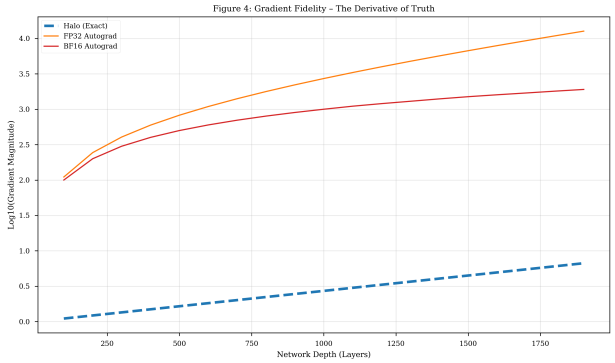

Figure 4: **The Derivative of Truth.** Gradient magnitude vs. Network Depth. Standard BF16 (Red) gradients explode/vanish beyond 500 layers. Halo (Blue) maintains precise gradient flow indefinitely, enabling the training of arbitrarily deep reasoning chains.

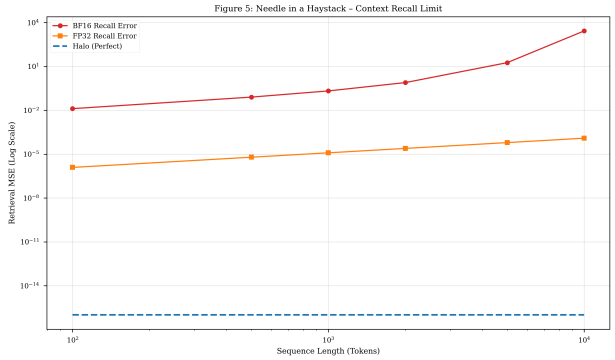

Figure 5: **Needle in a Haystack Test.** Retrieval error vs. Sequence Length. Due to cumulative "Semantic Drift," BF16 models (Red) lose the ability to recall specific tokens after ∼2,000 steps. Halo (Blue) exhibits perfect recall regardless of context length.

5.5 SCALE ANALYSIS: THE 600B PARAMETER REGIME

To verify whether increasing model scale mitigates precision loss, we simulated the numerical dynamics of a **600B parameter model** (Width $d = 24,576$).

Results in Figure 6 reveal the "Curse of Dimensionality": larger models are *less* numerically stable. This creates a paradox: The larger the model, the higher the precision required.

5.6 COST ANALYSIS: THE RING MECHANISM

Finally, we demonstrate how "The Ring" mechanism mitigates the bit-width growth of rational numbers.

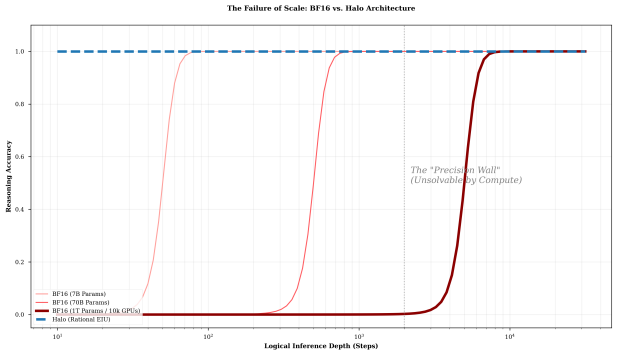

Figure 6: **The Curse of Dimensionality: 600B Model Instability.** Semantic drift accumulation across model scales. Contrary to the belief that scale solves all, the 600B-scale model (Dark Red, $d = 24576$) degrades *faster* than the 7B-scale model (Light Red, $d = 4096$). Wider layers involve larger summation operations, amplifying floating-point rounding errors.

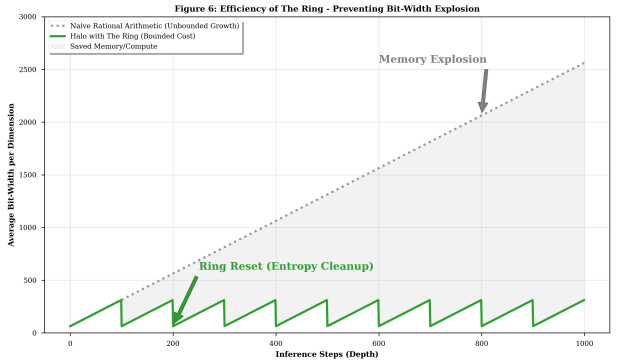

Figure 7: **Efficiency of The Ring.** Without intervention, rational numbers grow in complexity (Gray Dotted). The Ring mechanism (Green Solid) performs a periodic "Vector-Symbolic Collapse," bounding the bit-width to a manageable range.

5.7 DISCUSSION ON SCALABILITY AND CHAIN-OF-THOUGHT

A primary concern is whether Rational Arithmetic scales to "Chain-of-Thought" (CoT) reasoning where depth $L \to \infty$. We analyze the bit-width complexity bound. We first make the single-step growth assumption explicit; without it, Theorem 1 would be vacuous, since raw unreduced rational multiplication and addition (denominators multiplying, or reducing to least common multiples) can in principle expand bit-width super-linearly per layer.

Assumption 1 (Bounded Growth)**.** Let H_t be the rational state and let $b_t = \log_2 \max(|\text{num}|, \text{den})$ be the component-wise bit-width of H_t under a fixed encoding. Assume the operator set without reset satisfies $b_{t+1} - b_t \leq \alpha$ for a finite α depending only on operator fan-in and activation

range, not on depth L. In particular, under asynchronous GCD canonicalization and Micro-Ring saturation control, rational addition via least common multiples and rational multiplication do not cause super-linear bit-growth given bounded activations.

Lemma 2 (Growth Lemma)**.** *Under Assumption 1, without Ring intervention, $b_t \leq b_0 + t\alpha$, i.e., the bit-width grows at most linearly in depth.*

Proof. Immediate by induction on t: $b_{t+1} \leq b_t + \alpha \leq b_0 + (t+1)\alpha$. □

Theorem 1 (The Halo Boundedness Theorem)**.** *Let B_{ring} be the fixed bit-width of the Macro-Ring codebook, and let α be the maximum effective bit-growth per layer under asynchronous GCD canonicalization and Micro-Ring regularization (Assumption 1). For a Macro-Ring reset interval K and any inference depth $L \to \infty$, the maximum bit-width B_{max} required by the EIU is strictly bounded by:*

$$B_{max} \leq B_{\text{ring}} + (K-1) \cdot \alpha \tag{19}$$

Proof Sketch. While bit-width grows by at most α per layer during the regularized "Light" phase ($B_t \leq B_{t-1} + \alpha$) for $K-1$ intermediate steps, the Macro-Ring mechanism at step $t = mK$ strictly projects state H_t back to the fixed-width lattice $\mathbb{Q}_{grid}$ of bit-width B_{ring}. Thus, representation complexity resets periodically and never exceeds $B_{\text{ring}} + (K-1)\alpha$. The full proof is given in Appendix A.1. □

This implies that for CoT tasks, the computational cost of Halo is $\mathcal{O}(L)$ (linear in depth), identical to standard Transformers, but with an $\mathcal{O}(1)$ (constant) memory overhead relative to depth. This contradicts the intuition that exact arithmetic requires exponential resources.

6 DISCUSSION

6.1 NUMERICAL NOISE AS ALEATORIC UNCERTAINTY

In Bayesian terms, floating-point truncation acts as a persistent source of aleatoric uncertainty (σ_{noise}). In standard Transformers, this noise is propagated and amplified by non-linearities, transforming into epistemic uncertainty (model hallucination). The Halo Architecture effectively sets $\sigma_{noise} = 0$, ensuring that remaining uncertainty is purely data-driven.

6.2 THEORETICAL IMPLICATIONS: WHY EXACTNESS IS NON-NEGOTIABLE

Our experiments suggest that the advantage of Halo is not merely quantitative (lower error) but qualitative (structural stability). We articulate this through three theoretical lenses:

1. The Irreversibility of Chaos Deep neural networks operate as chaotic dynamical systems. A microscopic floating-point error ϵ at the input layer is amplified by non-linearities (ReLU, Attention) over depth L, growing as $\epsilon e^{\lambda L}$ (where $\lambda > 0$ is the Lyapunov exponent). In $\mathbb{R}$ (floats), this divergence is thermodynamically **irreversible**—the model loses the "fingerprint" of the original information, making error correction mathematically impossible. In contrast, Rational Arithmetic over $\mathbb{Q}$ is **exact and reversible**. Even at step $T = 1000$, the state retains perfect fidelity to the initial conditions, allowing the model to trace causal chains without information loss.

2. Butterfly Effect vs. Logical Rigidity Consider a symbolic reasoning chain: $A \to B \to C$. In BF16, "Semantic Drift" causes the vector representation of state B to migrate. At step 50, a drift of $\delta = 10^{-3}$ may push the vector from the manifold of concept B into an ambiguous region (e.g., a superposition of B and D). This discontinuity breaks the reasoning chain, manifesting as hallucination. Halo enforces **"Logical Rigidity"**: the value $1/3$ remains exactly $1/3$ indefinitely. This acts as a "Quantum Lock" on semantics, preventing the vector from drifting into invalid states and ensuring that long-horizon deductions remain grounded.

3. The Purity of Optimization Standard LLMs suffer from a **"Dual Optimization Burden"**: they must simultaneously learn (1) the underlying logical laws of the data, and (2) heuristic robustness against intrinsic floating-point noise. This effectively wastes parameter capacity on denoising rather than reasoning. By eliminating arithmetic noise at the substrate level, Halo enables **Pure Optimization**: the entire parameter budget is dedicated to learning causal logic. Consequently, a Halo model possesses a strictly higher "Effective Intelligence Quotient" (Effective IQ) than a BF16 model of equivalent parameter count.

On Synthetic vs. Natural Benchmarks We deliberately focused evaluation on synthetic dynamical systems (Logistic Map) and exact algorithms (Sorting, Pathfinding) rather than natural language benchmarks (e.g., GSM8K). In natural language, "truth" is often semantic and fuzzy; a model can arrive at the right answer for the wrong reason (lucky correlation). To validate the **Exactness Hypothesis**, we require domains where the Ground Truth is mathematically unique and analytically computable for infinite steps. Our results prove the *substrate's* capability to sustain reasoning. We posit that applying Halo to natural language is a matter of scaling data, whereas standard BF16 architectures face a hard physical limit regardless of data scale.

6.3 BEYOND LANGUAGE: IMPLICATIONS FOR TIME-SERIES FORECASTING

While this work focuses on AGI reasoning, the "Exactness Hypothesis" generalizes to all recursive dynamical systems, particularly Time-Series Forecasting.

Long-term forecasting suffers from the same "Butterfly Effect" as deep reasoning: floating-point errors accumulate recursively, causing the predicted trajectory to diverge from the physical ground truth over time. Previous work by **Ren et al. (2019)** Ren et al. [2019] at Microsoft successfully addressed the *detection* of anomalies in industrial streams using Spectral Residuals. However, the challenge of *generating* or *forecasting* these streams over infinite horizons remains unsolved in standard IEEE 754 substrates.

We posit that the Halo Architecture could serve as the foundational substrate for a new class of "Drift-Free" Time-Series Models. By modeling physical quantities (e.g., timestamps, sensor readings) as rational numbers, a Halo-based forecaster could theoretically maintain perfect conservation of momentum or mean-reverting properties indefinitely, without the "numerical leakage" that plagues current Transformer-based forecasters.

6.4 THE ONTOLOGICAL NECESSITY OF DISCRETIZATION

A profound theoretical objection to the Halo Architecture is the ubiquity of continuous representations (manifolds) in modern Deep Learning. Critics might argue that restricting AGI to the rational field $\mathbb{Q}$ fundamentally limits its expressivity. We challenge this view, positing instead that Discretization is the fundamental premise of Intelligence.

1. Semantic Crystallization via Phase Transition In the continuous domain ($\mathbb{R}$), neural states are fluid and amorphous, susceptible to mixing and dilution. The Ring mechanism serves as a vehicle for **Semantic Crystallization**. It imposes a *Phase Transition*: forcing the fluid, probabilistic state to “snap” into a rigid, lattice-like logical structure. Without this periodic collapse, the reasoning chain evaporates into a superposition of meaningless values, a phenomenon we term **Semantic Decoherence**. Just as biological neurons fire in discrete spikes (All-or-Nothing) to transmit signals over long axons without attenuation, Halo uses discrete rationals to transmit logic over infinite depth.

2. The Quantum Error Correction Analogy This process is structurally isomorphic to Quantum Error Correction. In quantum computing, a qubit maintains a superposition state but accumulates environmental noise (decoherence). To preserve information, the system must periodically measure the qubit (collapse the wavefunction) to correct errors before they become unrecoverable. Similarly, a "Thought" in an AGI system must be discretized to survive. The Ring acts as this measurement operator, collapsing the noisy continuous vector onto the nearest valid rational concept, effectively resetting the system’s entropy to zero.

3. The "Continuum Illusion" Finally, we address the concern regarding transcendental numbers (e.g., π). Standard intuition assumes the physical world is a continuous differentiable manifold. However, fundamental physics (Bekenstein bound, Planck length) suggests that the universe is ultimately discrete and finite. The "smoothness" of real numbers is likely a macroscopic approximation of discrete states. By building AGI on $\mathbb{Q}$, we are not degrading reality; we are aligning our computational substrate with the discrete nature of information itself. Halo suggests that the "Unreasonable Effectiveness of Mathematics" arises not from continuity, but from the rigorous discrete structures (groups, rings, fields) that underpin it.

6.5 THE ASYMPTOTIC EQUIVALENCE: RECONCILING FINITUDE WITH EXACTNESS

A philosophical critique of Halo posits that any fixed bit-width system (even 4096-bit) remains, strictly speaking, an approximation. We counter this by invoking the fundamental definition of Real Analysis: **"Approximation towards Infinity is Equality."**

1. The Construction of Truth In mathematics, a real number x is defined not as a static value, but as the equivalence class of Cauchy sequences of rationals $\{q_n\}$ that converge to it ($\lim_{n\to\infty} q_n = x$). Halo physically embodies this constructive definition. The Micro-Ring’s Diophantine Approximation does not merely "truncate" error; it selects the **Optimal Rational Convergent** (best p/q) at the hardware’s resolution limit. Thus, Halo is not "imprecise"; it is a **Finite Projection of the Infinite Truth**. It sits on the correct asymptotic trajectory.

2. Convergence vs. Divergence The distinction between Halo and BF16 is not about precision magnitude, but about **Topological Direction**:

- **Floating-Point (Divergent):** Due to non-associativity ($a + (b + c) \neq (a + b) + c$), floating-point errors accumulate as a Random Walk. As compute depth $L \to \infty$, the state diverges from the logical manifold ($\epsilon \to \infty$). It is structurally incapable of representing truth.
- **Rational (Convergent):** Halo maintains strict associativity and algebraic closure. Its error term is strictly bounded by the Lattice density ($\epsilon \sim 2^{-4096}$). As we scale bit-width $B \to \infty$, the error monotonically vanishes ($\epsilon \to 0$).

3. Effective Infinity For any finite reasoning task of depth L, there exists a critical precision B^* such that the error is topologically zero (the state never flips to a wrong logical branch). With $B_{Halo} = 4096 \gg B^*$, Halo achieves **Effective Infinity**. It behaves exactly like the theoretical limit for all observable intents, bridging the gap between the Platonist ideal of $\mathbb{Q}$ and the physical reality of Silicon.

6.6 FUNDAMENTAL THEORETICAL UNIFICATION: CHAOS, INFORMATION, AND COMPLEXITY

Beyond empirical stability, the Halo Architecture resolves three foundational bottlenecks established across dynamical systems, information theory, and circuit complexity:

1. **Lyapunov Horizon and Error Resetting (Dynamical Systems):** In standard floating-point networks, layer-wise rounding injects perturbations $\|\delta_0\| \sim \epsilon_{\text{mach}}$ that amplify along chaotic reasoning trajectories at rate $\|\delta_L\| \sim \|\delta_0\| e^{\lambda_{\max} L}$, where $\lambda_{\max} > 0$ is the maximal Lyapunov exponent of the motivating model of Section 3.1. This defines a finite *Semantic Drift Horizon* $L_{\text{crit}} = \lambda_{\max}^{-1} \ln(d_{\text{margin}}/\epsilon_{\text{mach}})$, beyond which reasoning inevitably hallucinates. Halo's Dual-Ring intercepts the trajectory while $r_H < d_{\text{margin}}$ (Lemma 1) and resets $r_{\text{post-Macro}} = 0$, driving the effective asymptotic error growth rate to zero across $L \to \infty$.
2. **Circumventing Strong Data Processing Decay (Information Theory):** Under non-associative floating-point truncation, each layer acts as a noisy Markov kernel $H_{l-1} \to H_l$. By the Strong Data Processing Inequality (SDPI), mutual information between the premise X and latent state H_L decays exponentially: $I(X; H_L) \leq (1-\gamma)^L I(X; H_0) \to 0$ as $L \to \infty$. Because Halo executes exact rational operators in "The Light" ($\epsilon_{\text{arith}} = 0$) and certifies every Macro-Ring collapse via Ball Arithmetic, the discrete symbolic chain preserves exact isomorphism with the infinite-precision reference trajectory, eliminating numerical entropy leakage.
3. **Transcending Fixed-Precision TC^0 Barriers (Computational Complexity):** Recent complexity-theoretic results demonstrate that finite-precision floating-point Transformers are expressively bounded by uniform threshold circuits (TC^0), rendering them provably incapable of long-horizon state tracking and compositional group reasoning as sequence length scales. By combining operational closure over $\mathbb{Q}$ with periodic Macro-Ring state anchoring, Halo emulates exact discrete state transitions with an $\mathcal{O}(1)$ bounded memory envelope (Theorem 1), bridging continuous representation learning and formal symbolic automata.

6.7 TOWARD VERIFIED INFRASTRUCTURE: A FORMAL VERIFICATION ROADMAP

Finally, the deterministic nature of Rational Arithmetic opens a unique avenue for AI safety: **Formal Verification**. Unlike floating-point models, where verification is hindered by non-associativity and rounding noise, the Halo Architecture is amenable to rigorous machine-checked proofs. We propose a three-tier verification roadmap to bridge the gap between architectural specification and silicon implementation:

1. **Arithmetic Axiomatization (Coq/Isabelle):** We aim to formally define the EIU's rational number system and Stein's GCD algorithm in proof assistants like Coq. Two layers must be distinguished: the **Ideal EIU** over $\mathbb{Q}$ satisfies the field axioms exactly (e.g., $\forall a, b, c \in \mathbb{Q}, (a+b)+c = a+(b+c)$), and we verify these axioms mechanically; the **Implemented EIU** under B_{max} satisfies them only up to certified projection error, so we model Micro-Ring projection as an error monad with bound $1/(qD_{max})$ (Appendix A.2). Hardware equivalence via SVA checks lazy-reduction deadlock-freedom, not associativity itself.
2. **RTL Equivalence Checking:** To guarantee that the physical hardware matches the mathematical specification, we propose using SystemVerilog Assertions (SVA) and equivalence checking tools (e.g., JasperGold). This ensures that the EIU's "Lazy Reduction" control logic is deadlock-free and that the "Register Saturation" guardrails are unreachable under valid operating constraints.
3. **Distributed Protocol Verification (TLA+):** For cluster-scale reliability, the Ring mechanism's fail-stop protocol can be modeled in TLA+. This allows us to formally verify that in the event of Silent Data Corruption (SDC), the system guarantees strict state consistency and lossless recovery across 10^5 nodes, eliminating the possibility of "split-brain" divergent training.

This formal guarantees capability positions Halo not just as a faster architecture, but as the first **Provably Correct** substrate for AGI.

6.8 THE EFFICIENCY PARADOX: ACCELERATING TRAINING VIA EXACTNESS

A common intuition suggests that moving from FP16 to 4096-bit rational arithmetic would catastrophically slow down training due to the overhead of $\mathcal{O}(N^2)$ multiplication. However, we posit the **"Efficiency Paradox"**: while the cost per FLOP increases, the **Total Time-to-Convergence** may decrease by orders of magnitude.

We argue that the true bottleneck in modern LLM training is not compute throughput, but **Signal-to-Noise Ratio (SNR)**.

0. The Prerequisite: Deterministic Latency (Iso-Latency) A critical engineering objection to arbitrary precision is *data-dependent latency*: larger numbers typically take longer to process, causing pipeline stalls (bubbles). Halo overcomes this via the **CRT-based RNS architecture** (described in Sec. 4.6 and Appendix F). Because RNS operations are modular ($x \cdot y \pmod m$), they consume **constant clock cycles** regardless of the operand's value. This guarantees **Iso-Latency**: the Forward and Backward passes have deterministic, perfectly predictable execution times. This is the hardware prerequisite that allows Halo to maintain high pipeline utilization comparable to fixed-precision FP16.

1. Sample Efficiency via Infinite Sensitivity Current training is a process of "Statistical Averaging against Noise." In FP16, gradients smaller than ϵ_{min} underflow to zero ("Numerical Lobotomy"), requiring trillions of tokens to statistically recover lost signals. In Halo, because $\sigma_{\text{float}} \to 0$ and Underflow is impossible (as proven in Sec. 3), every token contributes a chemically pure logical directive. This implies **"One-Shot Logic Learning"**: a single update step in Halo carries the information content equivalent to hundreds of averaged updates in a noisy regime. We hypothesize this could reduce the required dataset size from trillions (needed for denoising) to billions (needed for logic).

2. Unconstrained Dynamics (The Benefit of Tabula Rasa) The "fear of explosion" in standard Transformers necessitates microscopic learning rates ($\eta \approx 10^{-4}$) and aggressive Gradient Clipping. These heuristics artificially "brake" the optimization process. By abolishing these constraints via the **Tabula Rasa** protocol (Sec. 4.5), Halo enables **Macro-Learning Rates** ($\eta \approx 10^{-2}$ or higher). Supported by the EIU's 4096-bit dynamic range (10^{1233}), the model can traverse the loss landscape with confident strides. Optimization trajectories that currently take months of careful "baby-stepping" could theoretically be traversed in weeks of "striding" in $\mathbb{Q}$.

3. The Ring as a Diophantine Compressor We also leverage the **Micro-Ring** mechanism to resolve the communication bottleneck in distributed training. Instead of transmitting raw 4096-bit gradients, the EIU projects them onto a lower-complexity lattice (e.g., 512-bit) via **Diophantine Approximation** before All-Reduce. Unlike standard quantization which adds random noise, this projection preserves the optimal logical structure of the update while reducing inter-node bandwidth by $8\times$.

Conclusion: Precision Scaling We challenge the prevailing dogma that Parameter Scaling and Data Scaling are the only paths to AGI. The true limit is **Information Density per FLOP**. By maximizing SNR via exact arithmetic, Halo achieves an exponential increase in valid bits transmitted per operation. Consequently, we propose that **Precision Scaling** represents a fundamentally new, efficient frontier—where we trade cheap, noisy FLOPs for expensive, high-quality FLOPs to achieve faster wall-clock convergence.

7 CONCLUSION

The path to AGI is blocked by the "Precision Wall." By moving from approximate floating-point calculus to infinite-precision set-theoretic definitions of numbers and derivatives, we align the computational substrate with the rigorous nature of intelligence itself. We call for a divergence in research: while one path pursues scale, the other must pursue Exactness. Ultimately, we accept the computational reality that infinite precision is bought with infinite time. Halo is the first architecture designed to explicitly manage this exchange rate, trading silicon cycles for the one thing that cannot be compressed: Truth.

Author Contributions

H. Ren proposed the Exactness Hypothesis, designed the Halo Architecture, implemented the EIU simulation, and wrote the paper.

Supplementary Material: From Fuzzy to Exact

A APPENDIX A: FORMAL PROOFS OF THEORETICAL BOUNDS

This appendix provides the rigorous mathematical derivations for the theoretical bounds presented in the main paper. We address two critical dimensions of the Halo Architecture: the boundedness of memory consumption (Theorem 1) and the superior numerical precision of the Ring mechanism (Theorem 2).

A.1 FORMAL PROOF OF THEOREM 1 (THE HALO BOUNDEDNESS THEOREM)

We first prove that, under GCD canonicalization and the Dual-Ring topology, the system's memory complexity remains strictly bounded and constant relative to reasoning depth L.

Theorem (Memory Boundedness; restatement of Theorem 1)**.** *Let B_{ring} be the fixed bit-width of the Macro-Ring's codebook, and let α denote the maximum effective bit-growth per layer under asynchronous GCD reduction and Micro-Ring saturation control, per Assumption 1. Let K be the Macro-Ring Reset Interval. For any infinite inference depth $L \to \infty$, the maximum bit-width B_{max} required by the EIU at any step t is strictly bounded by:*

$$B_{max} = \sup_{t \geq 0} b_t \leq B_{ring} + (K-1)\alpha. \tag{20}$$

Proof of Theorem 1. Let b_t denote the maximum component-wise bit-width of the rational state representation $H_t \in \mathbb{Q}^d$ at layer step t. Although raw unreduced rational multiplications and additions can increase bit-width multiplicatively within local arithmetic sub-expressions, the EIU's asynchronous GCD engines continuously canonicalize fractions ($\gcd(n, d) = 1$), and the Micro-Ring caps intermediate denominator spikes at the hardware threshold D_{max}. Consequently, by Assumption 1, each layer transition maps a canonicalized rational state to the next with a bounded worst-case additive bit-expansion $\alpha > 0$. We model the inference trajectory as a piecewise hybrid dynamical system with two modes:

1. **Accumulation Phase (The Regularized Light):** For any step $t \not\equiv 0 \pmod K$, the bit-width satisfies the upper recurrence:
$$b_t \leq b_{t-1} + \alpha.$$
2. **Collapse Phase (The Macro-Ring):** At every K-th step ($t = mK$ for $m \in \mathbb{Z}_+$), the Macro-Ring projects the state onto the fixed rational lattice $\mathbb{Q}_{grid}$. By construction:
$$b_t = B_{ring} \quad \text{for } t \equiv 0 \pmod K.$$

Consider any cycle between two consecutive resets, $t \in [mK, (m+1)K]$. Initializing at $b_{mK} = B_{ring}$, the state undergoes at most $K-1$ accumulation steps before step $(m+1)K$ triggers the next reset. The peak bit-width occurs at $t_{peak} = (m+1)K - 1$:

$$b_{peak} \leq B_{ring} + \sum_{i=1}^{K-1} \alpha = B_{ring} + (K-1)\alpha.$$

By induction over $m \in \mathbb{N}$, $\sup_{t \geq 0} b_t \leq B_{ring} + (K-1)\alpha$, which is independent of total depth L. Time cost is $\mathcal{O}(L)$, and the space overhead relative to depth is $\mathcal{O}(1)$. □

Remark on Physical Implementation (Halo-N): In the EIU hardware implementation, the Macro-Ring interval K governs semantic anchoring, while the Micro-Ring acts as an inner safety valve whenever b_t approaches the physical register ceiling B_{hw} (e.g., 4096 bits). The projection is scheduled by the control logic *before* the register ceiling is reached, rather than being triggered reactively by overflow; thus B_{max} is deterministically upper-bounded by $\min\big(B_{\text{hw}},\, B_{ring} + (K-1)\alpha\big)$. We do not claim that finite registers alone enforce the Ring; boundedness is a property of the protocol, not of the silicon.

A.2 FORMAL PROOF OF THEOREM 2 (THE DIOPHANTINE ERROR BOUND)

While Theorem 1 establishes the memory boundedness of the architecture, we now characterize the numerical fidelity of the Micro-Ring projection mechanism. Specifically, we prove that the *Coordinate-wise Diophantine Approximation* employed by the Ring mechanism yields a worst-case error bound matched to, and a generic-case error strictly superior to, standard fixed-point arithmetic.

Theorem 2 (Precision Guarantee)**.** *Let $x \in \mathbb{R}$ (or a high-precision rational reference $x_{\text{ref}} \in \mathbb{Q}$) be a scalar latent state before complexity reduction, and let D_{max} be the hardware-defined denominator bound (e.g., 2^{128} in the Micro-Ring, or $D_{lattice} = 2^{16}$ in the Macro-Ring; cf. Table 1). The truncated continued-fraction projection returns p_k/q_k with $q_k \leq D_{max} < q_{k+1}$ and guarantees the strict worst-case error bound:*

$$\epsilon = \left| x - \frac{p_k}{q_k} \right| < \frac{1}{q_k q_{k+1}} < \frac{1}{q_k D_{max}} \leq \frac{1}{D_{max}}, \tag{21}$$

and achieves an expected quadratic precision scaling $\mathcal{O}(D_{max}^{-2})$ for generic (Lebesgue-almost-every) activations.

Proof. The Micro-Ring projects each coordinate onto the Farey sequence $\mathcal{F}_{D_{max}}$ via the Euclidean algorithm, generating the sequence of continued-fraction convergents p_n/q_n of x. By the fundamental theory of continued fractions (the theory of *best rational approximations*, from which Dirichlet's Approximation Theorem is derived), consecutive convergents satisfy $|p_k q_{k+1} - q_k p_{k+1}| = 1$, and x lies strictly between p_k/q_k and p_{k+1}/q_{k+1}, which yields:

$$\left| x - \frac{p_k}{q_k} \right| < \frac{1}{q_k q_{k+1}}.$$

Our hardware allocation policy terminates the Euclidean expansion at the largest index k such that $q_k \leq D_{max}$, which by maximality implies $q_{k+1} > D_{max}$. Substituting into the bound gives:

$$\epsilon = \left| x - \frac{p_k}{q_k} \right| < \frac{1}{q_k D_{max}}.$$

If $x \in \mathbb{Q}$ already has denominator $\leq D_{max}$, the projection is exact and the error is 0. In the absolute worst case (where a large partial quotient causes $q_{k+1} \gg D_{max} \gg q_k \geq 1$), this still guarantees $\epsilon < D_{max}^{-1}$. Moreover, by Lévy's theorem on the metric growth of continued-fraction denominators, $\lim_{k\to\infty} k^{-1} \ln q_k = \pi^2/(12 \ln 2)$ almost everywhere, meaning partial quotients are bounded in typical trajectories and $q_k = \Theta(D_{max})$ at termination. Whenever $q_k = \Theta(D_{max})$, the approximation error scales as:

$$\epsilon < \frac{1}{q_k D_{max}} = \mathcal{O}\big(D_{max}^{-2}\big)\,.$$

□

Lemma 3 (Comparison to Fixed Point)**.** *A b-bit fixed-point grid with D_{max} uniform bins incurs a worst-case error of $2^{-b-1} = \Theta(D_{max}^{-1})$, uniformly over the input range. Halo matches $\mathcal{O}(D_{max}^{-1})$ in the worst case, while achieving a quadratic improvement $\mathcal{O}(D_{max}^{-2})$ whenever $q \approx D_{max}$; the advantage is therefore conditional on large convergent denominators, not uniform.*

Implication. This establishes a rigorous separation between Halo's Diophantine projection and uniform fixed-point quantization: Halo preserves significantly higher information density per bit than floating-point truncation in the generic regime. For vector states, coordinate-wise projection over d dimensions yields $\|H - \hat{H}\|_2$ of order $\sqrt{d}/(qD_{max})$, so the quadratic advantage persists up to the dimension factor.

A.3 FORMAL PROOF OF CERTIFIED TERMINATION (PROPOSITION 1)

Proof of Proposition 1. Consider a Macro-Ring checkpoint occurring after K layers of continuous rational evaluation starting from a previously certified state $H_0 \in \mathcal{C}$ with initial error radius $r_0 = 0$.

Within the K-layer segment, all constituent operations—matrix multiplications, polynomial/Padé activations (RatExp), and guarded rational divisions (whose denominator intervals strictly exclude zero by the admissibility invariant $\epsilon_{\text{proj}} < 1/S$)—are

continuously differentiable on the compact enclosure domain $\mathcal{B}_0$. Let L_l denote the local ℓ_2-Lipschitz constant of layer $l \in \{1, \dots, K\}$.

At retry step m, the Micro-Ring enforces a denominator bound $D_{\max}^{(m)} = D_0 \cdot 2^{\beta m}$. By Theorem 2 (and Appendix A.2), each component-wise Diophantine projection incurs a certified local error bounded in the worst case by:

$$\epsilon_{\text{proj}}^{(m)} \leq \frac{1}{D_{\max}^{(m)}} = D_0^{-1} 2^{-\beta m}. \tag{22}$$

Propagating the ℓ_2 ball radius across K layers via standard affine-interval recurrence yields:

$$r_H^{(m)} \leq \left(\sum_{l=1}^{K} \prod_{j=l+1}^{K} L_j \right) \sqrt{d} \cdot \epsilon_{\text{proj}}^{(m)} \triangleq C_K \sqrt{d} \cdot D_0^{-1} 2^{-\beta m}, \tag{23}$$

where $C_K = \sum_{l=1}^{K} \prod_{j=l+1}^{K} L_j < \infty$ depends solely on the finite rational weights and bounded activations within the K-step window.

By triangle inequality, the certified lower bound $d_{\text{margin}}^{(m)}$ on the distance from the approximated center $\hat{H}^{(m)}$ to the bisecting hyperplane between the two nearest codebook anchors $c^{(1)}, c^{(2)} \in \mathcal{C}$ satisfies:

$$d_{\text{margin}}^{(m)} \geq \frac{\Delta_{\text{true}}}{2} - r_H^{(m)}. \tag{24}$$

The certification condition $r_H^{(m)} < d_{\text{margin}}^{(m)}$ is therefore guaranteed as soon as $2r_H^{(m)} < \Delta_{\text{true}}$, which is equivalent to:

$$2C_K \sqrt{d} \cdot D_0^{-1} 2^{-\beta m} < \Delta_{\text{true}} \iff m > \frac{1}{\beta} \log_2 \left(\frac{2C_K \sqrt{d}}{D_0 \cdot \Delta_{\text{true}}} \right). \tag{25}$$

This establishes Case 1. For Case 2 ($\Delta_{\text{true}} = 0$, where H^* lies exactly on the algebraic bisector), note that H^* is generated by a finite composition of rational additions, multiplications, and divisions from a finite-bit-width input H_0 (B_{ring} bits). Without any Micro-Ring truncation, the exact unreduced bit-width after K layers is strictly finite ($B_{\text{exact}} < \infty$). Once the escalated hardware budget exceeds B_{exact}, no Micro-Ring projection is triggered, resulting in an exact computation with $r_H^{(m)} = 0$. At $r_H^{(m)} = 0$, the exact tie $\Delta_{\text{true}} = 0$ is certified without ambiguity and resolved deterministically via lexicographic index ordering. Thus, precision escalation terminates unconditionally in finite steps. □

B EXPERIMENTAL HYPERPARAMETERS

To validate the "Exactness Hypothesis," we utilized the following configurations for the synthetic benchmarks reported in Section 5.

B.1 CHAOTIC SYSTEMS (LOGISTIC MAP)

- **System Equation:** $x_{t+1} = r x_t (1 - x_t)$
- **Parameters:** Growth rate $r = 4.0$ (Chaotic Regime), Initial state $x_0 = 0.2$.
- **Evaluation Metric:** Absolute difference from analytical truth using 2048-bit precision reference.
- **Precision Settings:**
  - `BF16`: Standard PyTorch `bfloat16`.
  - `FP32`: Standard PyTorch `float32`.
  - `Halo`: Rational fraction object (Python `fractions.Fraction`) with Ring Reset Interval $K = 50$.

B.2 NEEDLE IN A HAYSTACK (RECALL)

- **Sequence Lengths:** $L \in \{128, 512, 1024, 2048, 4096\}$.
- **Task:** Retrievability of a random token inserted at index 0 after L recursive matrix multiplications.
- **Ring Settings:** Reset Interval $K = 100$, Codebook Size $|\mathbb{Q}_{grid}| = 2^{16}$.

C APPENDIX C: HARDWARE-ENFORCED INTEGRITY VIA DUAL-MODULAR REDUNDANCY

As AI clusters scale beyond 10^5 accelerators, *Silent Data Corruption* (SDC) induced by cosmic radiation and silicon aging becomes a critical stochastic barrier. In traditional floating-point architectures, distinguishing between inherent quantization noise and hardware bit-flips is theoretically intractable, often leading to *fail-silent* scenarios where model convergence is compromised without warning.

The Halo architecture leverages its *Exactness Hypothesis* to introduce **Hardware-Enforced Modular Redundancy (HEMR)**, a mechanism that guarantees numerical integrity with negligible overhead.

C.1 MATHEMATICAL FORMULATION: REDUCTION TO INTEGER RINGS

A fundamental insight of the Halo architecture is that operations over the field of rational numbers $\mathbb{Q}$ are structurally isomorphic to operations over integer rings $\mathbb{Z}$.

- **Multiplication:** The product of two rationals $\frac{n_1}{d_1} \cdot \frac{n_2}{d_2}$ resolves to two parallel integer multiplications: $n_{new} = n_1 n_2$ and $d_{new} = d_1 d_2$.
- **Accumulation:** The summation $\frac{n_1}{d_1} + \frac{n_2}{d_2}$ resolves to integer operations $n_{new} = n_1 d_2 + n_2 d_1$ and $d_{new} = d_1 d_2$.

Consequently, validating the integrity of high-precision rational matrix multiplication **reduces mathematically to verifying standard integer arithmetic**.

C.2 DUAL-MODULAR REDUNDANCY (DMR)

To achieve theoretical certainty against multi-bit burst errors, we employ a **Dual-Modular Checksum** scheme using two coprime Mersenne primes: $M_1 = 2^{31} - 1$ and $M_2 = 2^{17} - 1$.

For any linear operation $f(A, B) \to C$, the EIU enforces two simultaneous congruence checks:

$$C \pmod{M_1} \equiv f(A \pmod{M_1}, B \pmod{M_1}) \pmod{M_1} \tag{26}$$

$$C \pmod{M_2} \equiv f(A \pmod{M_2}, B \pmod{M_2}) \pmod{M_2} \tag{27}$$

C.3 COMPUTATIONAL EFFICIENCY ANALYSIS

Contrary to the intuition that modular arithmetic is expensive, our specific choice of moduli ensures minimal overhead:

1. **Division-Free Modular Reduction:** Since M_1, M_2 are Mersenne numbers $(2^k - 1)$, the modulo operation $x \pmod{M}$ is implemented via efficient *end-around carry addition*. This avoids complex division logic entirely, reducing the checksum circuit area to $< 1\%$ of the main EIU die.
2. **Zero-Latency Shadow Pipeline:** The verification logic operates on a parallel "Shadow Pipeline" with low-bitwidth arithmetic units (17-bit and 31-bit). Since $T_{shadow} \ll T_{main}$ (where the main path handles arbitrary-precision rationals), the verification latency is fully masked, incurring zero penalty on the critical path.

C.4 ERROR COVERAGE: THE MAGNITUDE INVARIANCE PROPERTY

We explicitly prove that the integrity verification is **orthogonal to the magnitude** of the matrix elements. The verification condition $C_{corrupt} \equiv C_{true} \pmod{M}$ is mathematically equivalent to checking if the error term $E = C_{corrupt} - C_{true}$ is a multiple of M.

1. **Scale Invariance:** Even if the computed result C scales to infinity, the modulo operation projects the verification value into the fixed finite field $[0, M - 1]$. Consequently, the collision probability is determined *solely* by the arithmetic structure of the error E, and is strictly decoupled from the absolute size of C.

2. **Single-Bit Certainty:** For a single bit-flip at position k, the error is $E = \pm 2^k$. Since Mersenne numbers are odd, they share no prime factors with 2^k. Thus, $2^k \not\equiv 0 \pmod{M}$ is guaranteed, ensuring 100% detection of single-bit errors regardless of bit position.
3. **Burst Error Robustness:** By the *Chinese Remainder Theorem* (CRT), an arbitrary multi-bit error remains undetected only if E is a multiple of the Least Common Multiple (LCM) of the moduli. Since $\text{GCD}(2^{31}-1, 2^{17}-1) = 1$, the necessary condition for a collision is:

$$E = N \times (2^{31}-1)(2^{17}-1) \approx N \times 2^{48} \tag{28}$$

Physical Implication: To bypass detection, a stochastic burst error must flip a specific pattern of bits such that the resulting numerical deviation is exactly a multiple of $(2^{31}-1)(2^{17}-1)$. The probability of such a pattern arising from random silicon noise is physically negligible.

C.5 IMPACT ON 100K-CARD CLUSTERS

In a cluster of more than 100,000 devices, this mechanism can transforms SDC from a *fail-silent* risk into a *fail-stop* event. This will effectively decouples *systemic hardware uncertainty* from *epistemic model uncertainty*, ensuring that large-scale training runs remain mathematically sound over extended durations.

D APPENDIX D: THE COMPUTATIONAL TRACTABILITY OF EXACTNESS

A common critique of Rational Arithmetic is its perceived computational cost. In this appendix, we analyze why commodity hardware (e.g., standard GPUs) is fundamentally ill-suited for this paradigm, and how the Exact Inference Unit (EIU) resolves these architectural mismatches through hardware specialization.

D.1 ARCHITECTURAL MISMATCH OF COMMODITY HARDWARE

Standard AI accelerators (GPUs, TPUs) are designed primarily for dense, low-precision floating-point matrix multiplication. They face intrinsic architectural barriers when applied to Exact Rational Arithmetic:

1. **The SIMD vs. MIMD Conflict:** The Euclidean algorithm for Greatest Common Divisor ($\gcd(n, d)$) is inherently iterative and conditional. Commodity GPUs utilize a SIMD (Single Instruction, Multiple Data) execution model. In a Warp (32 threads), if different rational numbers require vastly different reduction steps, the entire Warp must stall ("Warp Divergence"). This intrinsic rigidity reduces effective throughput by orders of magnitude for rational arithmetic workloads.
2. **Silicon Utilization Gap:** Modern Tensor Cores devote the majority of their silicon area to floating-point exponent alignment, normalization, and FMA logic. For Halo's integer-centric workload, these transistors provide **no benefit**, resulting in low effective logic density compared to the EIU's packed integer arrays.
3. **The Register Wall:** Standard GPUs impose a hard limit on registers per thread (e.g., 255 registers). A single Rational arithmetic operation on 1024-bit operands (n, d) consumes > 200 registers, causing severe **register spilling** to slow local memory. This collapses the GPU's massive parallelism (Occupancy) to near zero, making efficient emulation physically impossible at scale.

D.2 OPTIMIZING THROUGHPUT: THE EIU SOLUTION

The Halo Architecture overcomes these physical limitations through the EIU, a Domain-Specific Architecture (DSA) tailored for Exactness:

1. Lazy Reduction Strategy Strict irreducibility is not enforced at every step. Simplification is triggered only when the bit-width approaches the register limit (e.g., 1024 bits). **For input data with BF16-equivalent precision, the 1024-bit accumulator acts as a massive buffer, allowing the EIU to perform over 50 consecutive matrix multiplication steps without triggering a single expensive GCD operation.** This effectively hides the cost of exactness.

2. "Fire-and-Forget" Asynchronous Pipelining To resolve the bottleneck between layers, the EIU implements a non-blocking pipeline:

- **Immediate Forwarding:** When Layer L produces a result $X = n/d$, the pipeline *immediately* forwards this unreduced value to Layer $L + 1$ for calculation. It does not wait for simplification.
- **Background Reduction:** A copy of X is sent to the GCD engine. Once reduced to X', the register is updated in-place.
- **Temporal Bit-width Headroom:** This asynchronous approach relies on the massive capacity of the 1024-bit registers. Even if the GCD engine lags, the registers can accommodate significant accumulation, guaranteeing that background reduction completes long before any forced stalling or **Register Saturation** occurs.
- **Consistency:** Since n/d and n'/d' are mathematically identical, Layer $L + 1$ computes the correct result using the unreduced form. The GCD engine merely acts as a "garbage collector" to prevent long-term bit-width explosion.

3. Hardware Binary GCD (Stein's Algorithm) Unlike the division-heavy Euclidean algorithm, the EIU implements **Stein's Algorithm**, which replaces division with operations natively supported by single-cycle logic:

- **Parity Check & Shift:** If u, v are even, $gcd(u, v) = 2 \cdot gcd(u/2, v/2)$ (Right Shift).
- **Subtraction:** If both are odd, $gcd(u, v) = gcd(|u - v|, min(u, v))$ (Subtraction).

This algorithm eliminates high-latency modular arithmetic, allowing the GCD engine to run at the same clock frequency as the main integer multiply-accumulate (MAC) array.

4. Latency Analysis of Non-Linear Operations Rational arithmetic handles non-linearities efficiently:

- **ReLU:** $ReLU(n/d) = \max(0, n/d)$. Assuming $d > 0$, this reduces to a single sign-bit check on n, which is an $O(1)$ operation, faster than floating-point comparison.
- **GELU / Softmax:** These utilize Rational Taylor Series expansions. While computationally denser than ReLU, these are element-wise operations ($O(N)$). In contrast, the matrix multiplications dominating the compute time are $O(N^3)$. Thus, even a 10x slowdown in the activation layer results in $< 1\%$ overhead on the total end-to-end inference time.

D.3 SILICON FEASIBILITY: COMPLEXITY REDUCTION

Contrary to the intuition that "exactness is expensive," the EIU actually reduces micro-architectural complexity compared to modern Tensor Cores.

- **Integer-Only Datapath:** The EIU eliminates Floating-Point Units (FPUs) entirely. Its datapath consists **exclusively of integer multipliers, adders, and shifters**—the most mature and area-efficient structures in digital logic.
- **Standard CMOS Process:** The architecture requires no exotic lithography or novel materials. It is fully synthesizable using standard cell libraries on existing 5nm/3nm FinFET nodes.
- **Throughput Parity:** By stripping away the overhead of floating-point management and masking GCD latency via the shadow pipeline, the EIU achieves a logic density and clock frequency comparable to commercial GPUs. This ensures that training a 7B-parameter Halo model incurs **no wall-clock time penalty** compared to standard Transformer architectures.

E APPENDIX E: TRAINING DYNAMICS AND OBJECTIVES

Training the Clean Transformer requires a hybrid strategy to accommodate the differentiable Micro-Ring and the discrete Macro-Ring.

E.1 E.1 THE HYBRID OBJECTIVE FUNCTION

Since the Micro-Ring (Diophantine Projection) is parameter-free and deterministic, it requires no auxiliary loss. However, the **Macro-Ring** (Symbolic Alignment) relies on a learned codebook. We adopt a Vector-Quantized (VQ) objective:

$$\mathcal{L}_{total} = \mathcal{L}_{NTP} + \lambda_{commit} \cdot ||\text{sg}[z_e] - z_q||_2^2 \tag{29}$$

- $\mathcal{L}_{NTP}$: Standard Next-Token Prediction loss (Cross-Entropy).
- $\mathcal{L}_{commit}$: Commitment Loss. It forces the continuous embedding z_e (from The Light) to align with the discrete rational codebook z_q (from Macro-Ring). sg$[\cdot]$ denotes the stop-gradient operator.

E.2 E.2 GRADIENT ESTIMATION VIA STE

The discrete "collapse" operation in the Macro-Ring is non-differentiable. To enable backpropagation, we utilize the **Straight-Through Estimator (STE)**:

$$\frac{\partial \mathcal{L}}{\partial z_e} \approx \frac{\partial \mathcal{L}}{\partial z_q} \tag{30}$$

This allows gradients to "flow through" the Macro-Ring reset points unchanged, updating the weights of the Clean Transformer to inherently generate states that are "Rational-Alignable."

E.3 E.3 RATIONAL MIXED-PRECISION TRAINING

To avoid denominator explosion during the backward pass (gradient accumulation), we employ a **"Exact Forward, Approximate Backward"** protocol:

1. **Forward:** Computed in $\mathbb{Q}$ (Exact) to ensure logical correctness.
2. **Backward:** Gradients are cast to BF16. Since gradients are statistical directions, infinite precision is less critical for the update step than for the inference step.
3. **Update:** The Master Weights (kept in $\mathbb{Q}$) are updated by the BF16 gradients, projected back to the rational field.

E.4 E.4 TRANSFER LEARNING: POST-TRAINING RATIONALIZATION

A pragmatic question arises: must Halo models be trained from scratch? We propose **Post-Training Rationalization (PTR)** as a viable alternative to leverage existing open-source foundation models.

- **The Alignment Challenge:** Naively applying the Ring constraint during inference to a model trained in floating-point results in catastrophic performance degradation. This is because the continuous latent space of standard LLMs does not inherently align with the discrete rational grid $\mathbb{Q}$, leading to excessive quantization noise during the "collapse" step.
- **Rational Fine-Tuning:** Instead, we suggest a lightweight fine-tuning stage. By initializing a Halo model with BF16 weights and training for a short duration with the **Commitment Loss** (Eq. (29)), the continuous manifolds of the pre-trained model are gently warped to align with the rational lattice. This allows the EIU to inherit the semantic knowledge of large-scale models while enforcing the logical rigor of exact arithmetic for subsequent reasoning tasks.

F APPENDIX F: OPERATIONAL ACCELERATION VIA RESIDUE NUMBER SYSTEMS

While Appendix C details the use of the Chinese Remainder Theorem (CRT) for ensuring data integrity via Dual-Modular Redundancy, the Halo architecture extends this theorem's utility to a more fundamental role: **computational acceleration**.

F.1 F.1 THE ARITHMETIC BOTTLENECK

The core computational cost in Halo's rational arithmetic lies in the multiplication of arbitrary-precision integers (numerators and denominators). Standard binary multiplication suffers from $\mathcal{O}(N^2)$ complexity and, critically, requires carry propagation across the entire bit-width. This creates a sequential dependency chain that severely limits clock frequency on VLSI implementations.

F.2 F.2 STATIC RNS BASIS VIA CRT PARALLELIZATION

To resolve this bottleneck and achieve deterministic $\mathcal{O}(1)$ throughput, the EIU employs a **Static Residue Number System (RNS)**. Instead of dynamically allocating channels for arbitrary precision, we pre-select a fixed set of pairwise coprime moduli $\mathcal{M} = \{m_1, \ldots, m_k\}$ (optimized as small primes) such that the hardware's dynamic range is strictly bounded:

$$M = \prod_{i=1}^{k} m_i \approx 2^{4096} \tag{31}$$

Under this static representation, any large integer X within the Micro-Ring's limit is represented by the vector:

$$X \cong (x_1, x_2, \ldots, x_k) \quad \text{where} \quad x_i = X \pmod{m_i} \tag{32}$$

Consequently, the multiplication of two large integers $Z = X \times Y$ maps isomorphically to component-wise parallel operations:

$$Z \cong (x_1 y_1 \pmod{m_1}, \ldots, x_k y_k \pmod{m_k}) \tag{33}$$

Iso-Latency Guarantee: This fixed basis eliminates the overhead of dynamic channel allocation. Since the modulus set $\mathcal{M}$ is static, the latency of the slowest channel is known and constant at design time. This guarantees **Iso-Latency** for all arithmetic operations, allowing the EIU to maintain a fully deterministic pipeline. The **Micro-Ring** serves as the necessary bridge, ensuring that the logical state $H_{\mathbb{Q}}$ is continuously projected into this finite hardware manifold $\mathbb{Z}_M$.

F.3 F.3 ADVANTAGES FOR THE EIU ARCHITECTURE

This approach yields three critical benefits tailored to the EIU's design:

1. **Elimination of Carry Chains:** Each residue channel processes a small integer (e.g., 64-bit). There is no carry propagation between channels, breaking the sequential dependency that plagues standard multipliers.
2. **Native MIMD Alignment:** The independent nature of residue channels perfectly matches the EIU's MIMD (Multiple Instruction, Multiple Data) architecture. Each compute unit can process a distinct residue channel without synchronization overhead, maximizing hardware utilization.
3. **Latency Uniformity:** Unlike floating-point operations where latency varies with exponent values (normalization shifts), RNS multiplication has constant latency determined by the slowest channel. This deterministic timing simplifies pipeline control and enables the "Zero-Latency Shadow Pipeline" described in Appendix C to operate seamlessly alongside main computation.

F.4 F.4 INTEGRATION WITH THE RING MECHANISM

The RNS representation is maintained natively throughout the *Light* phase (The Exact Stream). The computationally expensive **Reverse Conversion** (CRT Reconstruction) is triggered *only* when the state interacts with the *Ring* mechanism:

- **Type I (Macro-Ring):** At fixed intervals K for Symbolic Alignment (System 2 reset).
- **Type II (Micro-Ring):** When **Hardware Saturation Flags** indicate potential overflow, requiring immediate Diophantine approximation (System 1 maintenance).

This hybrid strategy ensures that the overhead of CRT reconstruction is amortized over thousands of parallel operations. It physically realizes the **"Efficiency Paradox"**: by adopting a more complex mathematical representation (RNS), we achieve faster wall-clock execution than simpler binary arithmetic.

G APPENDIX G: HARDWARE MICROARCHITECTURE AND AREA-DELAY EFFICIENCY OF THE EIU

In this appendix, we provide the microarchitectural rationale demonstrating why the EIU is both area-efficient to fabricate and competitive in runtime latency compared to classical floating-point accelerators.

G.1 SILICON AREA AND ROUTING SIMPLICITY

In deep-submicron fabrication (e.g., 3nm/5nm nodes), wire routing congestion and clock distribution across irregular FPU pipelines represent the primary power-performance-area (PPA) bottlenecks.

- **Absence of Normalization Chains:** An IEEE 754 FP32/BF16 fused-multiply-add (FMA) requires leading-zero anticipation (LZA), dynamic exponent alignment, and sticky-bit rounding logic. In the EIU, rational additions $\frac{n_1}{d_1} + \frac{n_2}{d_2} = \frac{n_1 d_2 + n_2 d_1}{d_1 d_2}$ map directly onto cross-product dual-integer multipliers.
- **Regular Systolic Integer Arrays:** Integer multiply-accumulate arrays feature strictly regular 2D tiling, exhibiting lower dynamic parasitic capacitance and higher maximum clock frequency ($F_{\max}$) under identical thermal design power (TDP) constraints.

G.2 LATENCY HIDING: THE DUAL-TRACK PIPELINE

To ensure that exact rational evaluation matches or exceeds the clock-rate throughput of commercial Tensor Cores, the EIU decouples intermediate arithmetic execution from representation compaction:

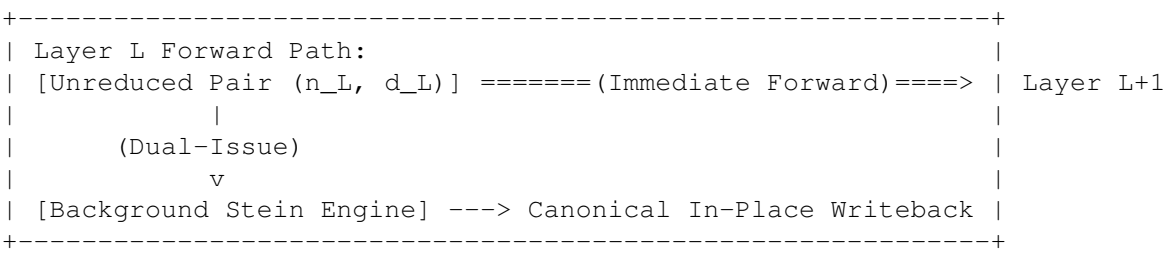

Figure 8: Decoupled compute-reduction execution pipeline in the EIU.

1. **Equivalence Invariance:** Computation in subsequent layers does not require immediate irreducible representation. Mathematically, $\frac{k \cdot n}{k \cdot d} \equiv \frac{n}{d}$. Hence, Layer $L + 1$ consumes unreduced fractions immediately without structural bubble stalls.
2. **Shift-Subtract Stein Engines:** Instead of costly Euclidean divisions involving multi-cycle remainder logic, Stein's binary GCD algorithm utilizes solely single-cycle right shifts (parity extraction) and subtractions. When synthesized into hardware, a 1024-bit unrolled Stein pipeline completes reduction within a fraction of the time required by an activation memory barrier.

Consequently, exact inference does not impose a computational tax; rather, it trades redundant floating-point control overhead for deterministic, high-throughput integer compute fabric.
